Three different muscle glycosylase have been found to cause congenital muscular dystrophy. Each appears to disrupt specific types of glycosylation, particularly of dystroglycan, leading to abnormal binding of dystroglycan to the extracellular basal lamina. The first identified was the "fukutin" protein; named after the disease subtype, Fukuyama congenital muscular dystrophy, that it causes. This congenital muscular dystrophy is seen almost exclusively in Japan and shows high serum creatine kinase levels at birth and atrophic brain. A protein identified based on structural homology to fukutin, fukutin-related protein, was also found to cause both congenital and adult onset forms of muscular dystrophy. Finally, mutations of yet another glycosidase, *O*-mannoside *N*-acetylglucosaminyltransferase, cause a syndromic type of muscular dystrophy dubbed "Muscle Eye Brain Disease."

NUCLEAR MEMBRANE DEFECTS: EDMD AND OCULOPHARYNGEAL DYSTROPHY

A rare X-linked-recessive disorder, EDMD, is clinically distinct from the dystrophinopathies resulting from the early presence of contractures and cardiac conduction defects requiring placement of a pacemaker. Linkage studies had mapped the gene to Xq28, and the responsible gene was found to encode a novel protein, emerin, which is a component of the nuclear envelope. A second nuclear membrane component, lamin A/C, was found to harbor missense mutations in autosomal-dominant families showing a phenotype indistinguishable

Table 112-1
Molecular Basis of the Muscular Dystrophies

Protein defect	*Disease*	*Onset of symptoms*	*Frequency*	*Characteristic clinical features*	*Gene mutations*	*Molecular diagnosis*
Dystrophin-deficiency	Duchenne muscular dystrophy	Childhood	1/3500 males (>90% of childhood-onset dystrophy)	Proximal weakness, calf hypertrophy, cardiomyopathy, 30% MR)	55% deletions	Mutation, linkage analysis, protein analysis of muscle biopsy
Abnormal dystrophin	Becker muscular dystrophy	Childhood-adult	1/20,000 males (50–70% of male teen /adult-onset dystrophy)	Proximal weakness, high CK cardiomyopathy	70% deletions	Mutation, linkage, protein analysis of muscle biopsy
Dystrophin mosaicism	Isolated female dystrophinopathy	Childhood-adult	1/100,000 females (10% of female dystrophy)	Proximal weakness, high CK, cardiomyopathy	60% deletions (heterozygote)	Protein, X inactivation, mutation, linkage
α-Sarcoglycan (adhalin)	SCARMD/LGM2D[a]	Childhood	<1/200,000	Proximal weakness, high CK	Missense	Protein followed by mutations[b]
β-Sarcoglycan	SCARMD/LGMD[a]	Childhood	<1/200,000	Proximal weakness, high CK	Missense	Protein followed by mutations[b]
δ-Sarcoglycan	SCARMD/LGMD2F[a]	Childhood	<1/200,000	Proximal weakness, high CK	Missense	Protein followed by mutations[b]
γ-Sarcoglycan	SCARMD/LGMD2C[a]	Childhood	<1/200,000	Proximal weakness, hyperCKemia	Nonsense	Protein followed by mutations
α2-Laminin (merosin)	Congenital muscular dystrophy	Neonatal	<1/200,000	Floppiness, high CK, white matter changes by MRI	Deletion[c] nonsense	Protein, prenatal of chorionic villi
Caplain III[d]	LGMD	Childhood-adult	1/100,000	Proximal weakness	Missense	Mutation
Emerin	X-linked EDMD	Childhood	<1/200,000	Contractures, proximal weakness, cardiac conduction defects	Missense	Mutation
Lamin A/C	Autosomal-dominant EDMD	Childhood		Contractures, proximal weakness, cardiac conduction defects	Missense	Mutation
DM kinase[e]	Myotonic dystrophy	Extremely variable	1/8000	Neonatal floppiness, childhood MR, adult distal wasting, cataracts, frontal balding	Expansion of CTG trinucleotide	Mutation
Dysferlin	Dysferlinopathy/myoshi myopathy/LGMD2B	Late teens-adulthood	<1/200,000	Distal and/or proximal weakness; inflammation on muscle biopsy; extremely elevated CK	Missense	Protein followed by mutations
Telethonin	Telethoninopathy /LGMD2G	Early teens	<1/200,000	Proximal and distal lower limb weakness; proximal upper limb weakness; foot drop; highly elevated CK	Not available	Not available
E3-Ub ligase	LGMD2H	Childhood	<1/200,000	Proximal lower limb weakness, neck weakness, weakness of facial muscles with "flat smile"; high CK	Missense	Mutation

(Continued)

Table 112-1 ***(Continued)***

Protein defect	*Disease*	*Onset of symptoms*	*Frequency*	*Characteristic clinical features*	*Gene mutations*	*Molecular diagnosis*
Fukutin-related protein	LGMD2I	Variable	<1/200,000	Proximal weakness; normal to high CK	Missense	Mutation
Myotilin	LGMD1A	Adulthood	<1/200,000	Proximal weakness; dysarthria; mildly elevated CK	Missense	Mutation
Lamin A/C	LGMD1B	Extremely variable	<1/200,000	Proximal lower limb weakness; contractures; cardiac arrhythmia in adulthood; risk of sudden cardiac death; mildly elevated CK	Missense	Mutation
Calveolin III	Calveolinopathy /LGMD1C	Early childhood	<1/200,000	Cramping; mild to moderate proximal weakness; high CK	Missense/ microdeletions	Mutation
Collagen alpha 1 chain Collagen alpha 2 chain Collagen alpha 3 chain	Bethlem myopathy	Early childhood	<1/200,000	Neonatal hypotonia; proximal weakness; contractures; normal to slightly elevated CK	Missense Missense Missense	Mutation Mutation Mutation
Fukutin	Fukuyama congenital muscular dystrophy	Neonatal	<1/200,000	Generalized weakness and hypotonia; contractures; lissencephaly; high CK	Insertion[f]; missense	Mutation
O-mannoside N-acetylglucosa minyltransferase	Muscle–eye–brain disease	Infancy	<1/200,000	Generalized weakness and hypotonia; contractures; lissencephaly; eye malformations	Nonsense, frameshift, splice site, insertion, missense	Mutation
O-Mannosyl transferase 1	Walker Warburg syndrome	Infancy	<1/200,000	Generalized weakness and hypotonia; contractures; lissencephaly; eye malformations; high CK	Nonsense, missense, frameshift	Mutation
Fukutin related-protein	MDC1C	Infancy	<1/200,000	Hypotonia; distal and proximal weakness; contractures; normal MRI and IQ; respiratory failure; macroglossia; high CK	Missense	Mutation
Integrin α7	Congenital muscular dystrophy with ITGA7 mutation	Infancy	<1/200,000	Proximal weakness; torticollis; congenital hip dislocation; mildly elevated CK	Deletion, missense	Mutation
Selenoprotein N	Congenital muscular dystrophy with early spine rigidity	Infancy	<1/200,000	Proximal and distal weakness with facial involvement; contractures; rigid spine; nocturnal hypoventilation; normal CK	Frameshift, missense	Mutation
α 1, 2, and 3 collagen VI	Ullrich congenital muscular dystrophy	Infancy	<1/200,000	Hypotonia; distal weakness greater than proximal; contractures; normal IQ; micrognathia; distal hyperextensibility; mildly elevated	Missense	Mutation

Unknown	Facioscapularhumeral muscular dystrophy	Childhood–adulthood	1/17,000	Weakness involving the face, scapula, upper arm, lower leg, and hip girdle; often asymmetric	Telomeric deletions	Mutation
Polyadenylate binding protein nuclear 1	Oculopharangeal muscular dystrophy	Late adulthood	Population specific ranging from 1/1000 to 1/100,000	Ptosis and dysphagia	Expansion of a GCG trinucleotide	Mutation

[a]Severe childhood-onset autosomal-recessive muscular dystrophy (SCARMD) and limb-girdle muscular dystrophy (LGMD) are generic descriptive diagnoses often used to describe these patients.

[b]Many muscular dystrophy patients show secondary deficiencies of sarcoglycan proteins. Thus, biochemical detection of a deficiency of a sarcoglycan protein most often does not reflect a primary deficiency (mutations) of that protein. For this reason, mutation analysis is suggested for a definitive diagnosis.

[c]Only a few mutations of the very large merosin gene have been identified to date.

[d]The clinical and molecular features of dystrophy associated with Calpain III mutations have not yet been well defined. A multiple gene (digenic) inheritance has been proposed.

[e]The molecular pathogenesis of myotonic dystrophy is not well understood. The disease is clearly caused by the expansion mutation in the 3′ UTR of the kinase gene; however, it is not clear what genes, RNAs, or proteins are altered by this expansion.

[f]The insertion mutation in the fukutin gene is seen as a founder mutation and accounts for the majority of cases. Other rare mutations have been identified.

from X-linked EDMD. Both lamin A/C and emerin are expressed in most cells of the body, and the reasons for the muscle/heart-specific phenotypes are not understood. Importantly, different missense mutations of lamin A/C cause remarkably distinct phenotypes, including premature aging (progyria), lipodystrophy, heart failure, and peripheral neuropathy.

Oculopharyngeal dystrophy is a dominantly inherited disease that typically shows an onset after 60 yr of age, with progressive eye muscle and pharyngeal weakness, with difficulty swallowing and aspiration pneumonia. The cause of this disorder is the increase in the number of alanine residues in the amino terminus of the PAB2 gene. This increase in size of the poly-alanine stretch appears to change the solubility of the protein, and lead to intranuclear inclusions that increase as a function of age.

MYOTONIC DYSTROPHY

Myotonic dystrophy is the term used to describe one of the most common, and certainly the most variable, myopathic disorder. The moniker is more historical than descriptive; only a subset of patients shows myotonia or muscular dystrophy. Patients with this dominantly inherited disorder can present in the neonatal period (congenital myotonic dystrophy) with floppiness often requiring ventilator support, in childhood with mental retardation and characteristic facies (hatchet jaw, lowset ears), in adolescence with distal weakness and wasting, or in older age with cataracts and frontal balding. The disease and corresponding severity have been strongly associated with an unstable trinucleotide repeat on the short arm of chromosome 19: repeats of many thousands of base pairs are associated with early onset severe disease and shorter repeats associated with later onset milder disease. The repeat length changes between parent and offspring (meiotic instability) predominantly when the disease is passed through the mother, as well as within a patient (mitotic or somatic instability), such that muscle tissue has longer repeats than are present in other tissues.

The CTG repeat expansion is in the 3′ untranslated region of a novel cAMP kinase gene (DM kinase), and one assumption is that the repeat alters the expression of the kinase protein, leading to expression of disease. However, the dominant inheritance (patients are heterozygotes, with a normal kinase gene in addition to the one containing the expansion mutation) and lack of sequence alterations in protein expressed by the mutant gene seem inconsistent with the dramatic variability of the clinical disease. The molecular pathogenesis results from changes in the solubility and distribution of the CTG-containing mRNA, leading to inappropriate regulation of many different mRNAs, apparently through abnormal mRNA splicing.

Facioscapulohumeral muscular dystrophy is one of the more common dominantly inherited muscular dystrophies and shows preferential involvement of facial and upper-girdle muscles. The disorder is variable in severity, although most patients present in the second decade or later. The disease is strongly associated with alterations of the telomere of the long arm of chromosome 4. However, no specific gene has been implicated in the pathogenesis.

113 Channelopathies of the Nervous System

STEPHEN C. CANNON

SUMMARY

Ion channels are integral membrane proteins that form water-filled pores and allow the rapid passage of ions across cell membranes. The importance of ion-channel function in health and disease states has long been recognized, particularly in medical therapeutics. Many drugs act directly on ion channels, including local anesthetic agents, antiarrhythmics, antihypertensives, most antiepileptic drugs, and many psychoactive medications. Mutations of ion-channel genes have been established as the cause of several human diseases, including more than 30 disorders affecting excitability in nerve, muscle, or special sensory organs and disorders of epithelial transport affecting kidney, lung, or gut.

Key Words: Channelopathies; episodic ataxia; gating; hyperekplexia; hypokalemic periodic paralysis; idiopathic generalized epilepsy; ion channels; myotonia congenita; nervous system; permeation; skeletal muscle.

INTRODUCTION

Ion channels are integral membrane proteins that form water-filled pores and allow the rapid passage of ions across cell membranes. These conduits are crucial components of the molecular machinery required for the generation and propagation of electrical impulses in excitable tissues, such as nerve and muscle. The net movement of charged ions through channels is the source of the electrical current that changes the cell's membrane potential (Vm). Ion flux through channels may also function as a chemical messenger. For example, calcium entry initiates the secretion of transmitters or hormones, the contraction of muscle, or the transcriptional control of gene expression.

The importance of ion-channel function in health and disease states has long been recognized, particularly in medical therapeutics. Many drugs act directly on ion channels, including local anesthetic agents, antiarrhythmics, antihypertensives, most antiepileptic drugs, and many psychoactive medications. Acquired defects in channel function have been known for decades. Autoimmune responses toward ion channels may accompany cancer, as occurs in myasthenia gravis (antinicotinic acetylcholine receptor, AChR, antibodies associated with thymoma) or the Lambert-Eaton myasthenic syndrome (antibodies against P/Q-type calcium channels with lung carcinoma). Channels are also targets for potent venoms used to paralyze prey (e.g., scorpion or sea anemone) or for biological toxins such as saxitoxin, a potent blocker of sodium channels, which causes paralytic shellfish poisoning.

Mutations of ion-channel genes have been established as the cause of several human diseases, including more than 30 disorders affecting excitability in nerve, muscle, or special sensory organs and disorders of epithelial transport affecting kidney, lung, or gut. The molecular mechanisms underlying these so-called channelopathies are diverse and have included gain-of-function defects, dominant-negative loss-of-function defects from mutant subunits in a multimeric channel complex, or haploinsufficiency. The channelopathies of neurological interest include diseases affecting the central nervous system, the peripheral nervous system, and skeletal muscle. Most of the known channelopathies are inherited as dominant traits with high penetrance, which facilitate the identification of causative mutations by linkage analysis and positional cloning. Another common feature of channelopathies affecting excitable tissues is the tendency to cause paroxysmal attacks, separated by long symptom-free intervals: epilepsy or migraine for CNS disorders, periodic paralysis or myotonic stiffness in skeletal muscle, and intermittent arrhythmia of the heart. Indeed, the discovery of disease genes in paroxysmal familial disorders has been hastened by searching databases for ion-channel genes as candidates within a region linked to the occurrence of the phenotype.

FUNCTIONAL PROPERTIES OF ION CHANNELS

The molecular pathogenesis underlying a particular channelopathy is often readily apparent from the extensive body of knowledge on the functional behavior of a channel and its role in regulating cellular excitability. This level of understanding is particularly well developed for the channelopathies of skeletal muscle, wherein the cell type is relatively uniform and the circuit considerations are much simpler than in the CNS.

Two fundamental properties of ion-channel behavior, *permeation* and *gating*, determine how a particular channel influences cellular excitability. The selective permeability of a channel allows some ions to pass through the pore to the relative exclusion of others. For example, potassium (K) channels are so named because they conduct potassium ions 100 times more readily than

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

sodium ions. This selectivity, in combination with the asymmetric distribution of ions between the intracellular and extracellular compartment, sets the *reversal potential* of the open channel. The reversal potential is the membrane voltage at which the net current through the channel is zero. The significance of the reversal potential is that it equals voltage toward which the Vm moves whenever ionic current flows through the channel. Thus, it is the permeation features of a channel that determine whether its actions are excitatory or inhibitory toward generating an action potential.

Channel gating is the second fundamental property and refers to the transitions between conducting and nonconducting conformations of the channel, akin to the notion of a gate that opens and closes access to the pore. Channels rapidly fluctuate between open and shut on a millisecond time-scale. Although the state of a channel (open or shut) at any instant is random, the average behavior is well defined and can be quantified as an open probability. The combination of open probability and density of channels in the membrane determines the overall influence that a particular type of channel has on setting the Vm. To a first approximation, the Vm is a weighted average of the reversal potentials for all the channel types in a cell, with the weights being the product of the open probability times the number of channels. A channel's open probability may be modulated by membrane voltage, ligand binding, mechanical stress, or intracellular messengers such as Ca^{2+} or cyclic nucleotides. In a resting cell, most channels are *closed* and the Vm is about –65 mV. Depolarization, ligand binding or some other stimulus may *activate* the channel and increase its open probability. In the continued presence of the stimulus, most channels will shut to an *inactive* state from which further opening cannot be induced until the stimulus is removed and channels are allowed to recover to the resting closed state.

The mutations that underlie channelopathies may either result in a nonfunctional protein incapable of forming a transmembrane pore, or produce a channel with altered functional properties. Expression studies have shown that gating is commonly affected by disease-associated mutations, whereas ionic selectivity is usually unaltered. The high resolution patch-clamp recordings of ionic currents, along with extensive characterization of wild-type channels, has enabled the detection of subtle alterations in channel gating, which can have dramatic effects on cellular excitability. The identification of specific defects in mutant channel behavior also provides a rational basis for designing therapeutic intervention. In general, disease-associated mutations tend to produce aberrant cellular depolarization, either through gain-of-function defects in sodium channels or loss-of-function defects in potassium or chloride channels.

CHANNELOPATHIES OF SKELETAL MUSCLE

The first inherited ion-channel disorders discovered in humans were those affecting skeletal muscle. This group of diseases represents one of the best examples of tracing disease pathomechanism from gene defect to altered protein function, to disrupted muscle excitability, and finally clinical phenotype.

The fidelity and speed of skeletal muscle contraction depend critically on the electrical excitability of the muscle fiber. Acetylcholine released at the motor neuron terminal binds to the postsynaptic AChR and produces a local depolarization, the endplate potential (EPP). In healthy muscle, the EPP exceeds the threshold to generate an action potential (safety factor), thereby ensuring the propagation of an impulse that travels longitudinally down the fiber and inward along the transverse tubules where depolarization elicits Ca^{2+} release from the sarcoplasmic reticulum. Molecular genetic defects in the machinery to generate the EPP result in a use-dependent breakdown of impulse initiation in the muscle, which presents clinically as the pathological fatigue in myasthenic weakness. Other disorders are caused by a primary defect in muscle membrane excitability, even in the presence of a normal EPP (Table 113-1). This latter group of diseases is caused by mutations in voltage-gated ion channels of skeletal muscle, which may lead to transient inexcitability and weakness to produce familial periodic paralysis. Alternatively, muscle membrane excitability may be pathologically enhanced such that a single EPP elicits a burst of repetitive discharges and the sustained involuntary after contractions of myotonia.

CONGENITAL MYASTHENIC SYNDROME: ACETYLCHOLINE RECEPTOR The cardinal feature of myasthenia is fatigability and weakness, especially for ocular and other cranial muscles; more severe cases may also involve limb and trunk muscles. Myasthenia gravis is a sporadic autoimmune disorder of early midlife to late life wherein antibodies against the AChR compromise the EPP by decreasing the number of functional receptors. In contrast, the congenital myasthenic syndromes (CMS) present at birth or soon thereafter with weakness of ocular, bulbar, and respiratory muscles are not associated with antiAChR antibodies. Genetic defects of both pre- and postsynaptic components of the neuromuscular junction are established causes CMS, and this chapter focuses on those resulting from mutations of the AChR.

The nicotinic AChR of the neuromuscular junction is a heteropentamer of two α and one each of β-, δ-, and ε-subunits. In embryonic or denervated muscle, the ε-subunit is replaced by a γ-subunit. In CMS, mutations of these subunits may cause a deficiency of functional channels or produce a kinetic defect in channel behavior. Most low-expression mutations are from homozygous or heterozygous defects in the ε-subunit and result in mild symptoms. The relative high frequency and mild nature of the ε-subunit defects probably result from the ability of the fetal γ-subunit to substitute for the defective ε-subunit. Morphological studies for low-expression mutations show an increased number of endplates, with simpler and smaller folds and decreased AChR staining at the crests of the junctional folds.

CMS resulting from kinetic abnormalities in AChR function can be divided into *slow-channel* and *fast-channel* variants (*see* Table 113-1). Slow-channel CMS has dominant inheritance with selective weakness of neck, scapular, and finger extensor muscles. Single nerve stimulation evokes a prolonged oscillatory compound muscle action potential rather than the normal bi- or triphasic response. Most likely this abnormality arises from an EPP that outlasts the refractory period and thereby elicits several action potentials. In vitro microelectrode studies show prolonged endplate current responses. Single channel activity monitored with patch-clamp recording reveals spontaneous openings and prolonged opening events. Genetic analysis has identified missense mutations in the extracellular and transmembrane segments of each subunit (α, β, δ, ε) in slow-channel CMS, and expression assays demonstrate the amino acid substitutions are responsible for the altered kinetic behavior. The cationic overload caused by these gain-of-function mutations leads to a characteristic endplate myopathy with focal degeneration of junctional folds, loss of AChRs, degenerating organelles, and small vacuoles. Fast-channel CMS is a rare autosomal-recessive disorder wherein a null allele is paired with the

Table 113-1
Comparison of Weakness in CMS and Periodic Paralysis

	CMS		
Feature	*Slow-channel*	*Fast-channel*	*Periodic paralysis*
Inheritance	Dominant	Recessive	Dominant
Weakness			
Distribution	Neck, scapular, finger extension	Ocular, cervical, selected limb	Limb and torso, Bulbar sparing
Duration	Minutes	Minutes	Hours to days
Change in serum K^+	No	No	Yes
Electromyographic			
Compound muscle action potential	Decremental 2 Hz, prolonged with oscillations	Decremental 2 Hz after exercise	Normal repetitive stimulation, sustained decrease (minutes) after exercise
Myotonia	None	None	Occurs with some types
Electrophysiology			
EPP	Reduced amplitude, prolonged	Reduced amplitude, shortened duration	Normal
Resting membrane potential	Normal	Normal	Depolarized during attack
Channel defect	Acetylcholine receptor	Acetylcholine receptor	Sodium, calcium, potassium channel

missense mutation of the same subunit that results in very short-lived channel opening events. The endplate current decay is hastened, and miniature EPPs generated by spontaneous ACh-laden vesicle release are barely detectable. No morphological changes of endplate structure occur, and these patients have moderate to severe symptoms that respond partially to acetylcholinesterase inhibitors.

MYOTONIA AND PERIODIC PARALYSIS: DISORDERS OF SARCOLEMMAL EXCITABILITY The nondystrophic myotonias and periodic paralyses are rare inherited disorders of skeletal muscle, all grouped by the common feature that the primary abnormality is an alteration in the electrical excitability of the muscle fiber. Moreover, all of these disorders arise from mutations in voltage-gated ion channels.

Myotonia Congenita: Chloride Channel Myotonia congenita (MC) is the prototypical form of hereditary myotonia that presents with muscle stiffness from an inability to relax after voluntary contraction or after direct muscle percussion. The persistent contraction results from sustained bursts of muscle action potentials lasting many seconds beyond the cessation of motor neuron activity. Myotonia is most pronounced with the first forceful movements after a period of rest and diminishes with repeated activity (warm-up phenomenon). The autosomal-dominant form of MC was first recognized a century ago (Thomsen's disease). The recessive form of MC, termed recessive generalized myotonia or Becker's disease, causes more severe symptoms with secondary muscle hypertrophy and is more prevalent, but was not recognized until about 50 yr later.

MC was the first human disorder proven to be caused by an ion-channel defect. This discovery was made by studying the electrical properties of muscle isolated from goats with a hereditary form of myotonia that resembled dominant MC in humans. Intracellular microelectrode recordings revealed an abnormally high resting membrane resistance in myotonic muscle fibers. In a classic series of experiments, this high resistance was determined to be from a drastic reduction in the resting conductance to chloride ions. Because chloride equilibrates freely across the muscle membrane (approximately), the reversal potential for chloride equals the resting Vm. Therefore, at rest, there is no net chloride flux (current). Whenever the Vm shifts from its resting value, as with an action potential, very large chloride currents flow that drive Vm back to its resting value. Moreover, with each action potential, there is a rise in extracellular potassium produced by the outward potassium current that repolarizes the fiber to the resting Vm, especially in the diffusion-limited transverse tubules. An increase in extracellular potassium would tend to depolarize the fiber, and might trigger another action potential, if it were not for the large chloride current that drives Vm back to its previously established resting value. The chloride current has an essential role in stabilizing the resting potential of skeletal muscle. When normal muscle fibers from unaffected goats were bathed in a chloride-free ringer solution (thereby eliminating the possibility of chloride currents), they developed myotonic features. Pharmacological studies with channel blockers demonstrated that at least 80% of the chloride conductance must be blocked to produce myotonia. Subsequent to these goat studies, intracellular recordings from biopsied human intercostal fibers demonstrated a chloride conductance defect in both autosomal-dominant and autosomal-recessive MC.

In families with autosomal-dominant and autosomal-recessive myotonia congenital, more than 70 mutations in ClC-1, the predominant chloride channel in skeletal muscle, have been identified. The molecular pathogenesis of the autosomal-dominant and autosomal-recessive inheritance patterns has been explained by functional expression studies of mutant channels. The ClC-1 chloride channel is a homodimer. The mutations associated with the autosomal-recessive form of MC are not capable of forming functional chloride channels, nor do they interfere with the assembly and function of coexpressed wild-type channels. Haploinsufficiency is subclinical because more than 50% of the chloride conductance must be lost before a muscle fiber becomes myotonic. Many of these autosomal-recessive mutations are premature stops or splice site alterations resulting in nonfunctional truncated proteins. Missense mutations of ClC-1 associated with the autosomal-dominant form of MC often result in channels that remain shut unless depolarized to very positive potentials. Coexpression with wild-type channels produces an intermediate behavior because of the formation of heterodimers. The net result is a dominant negative

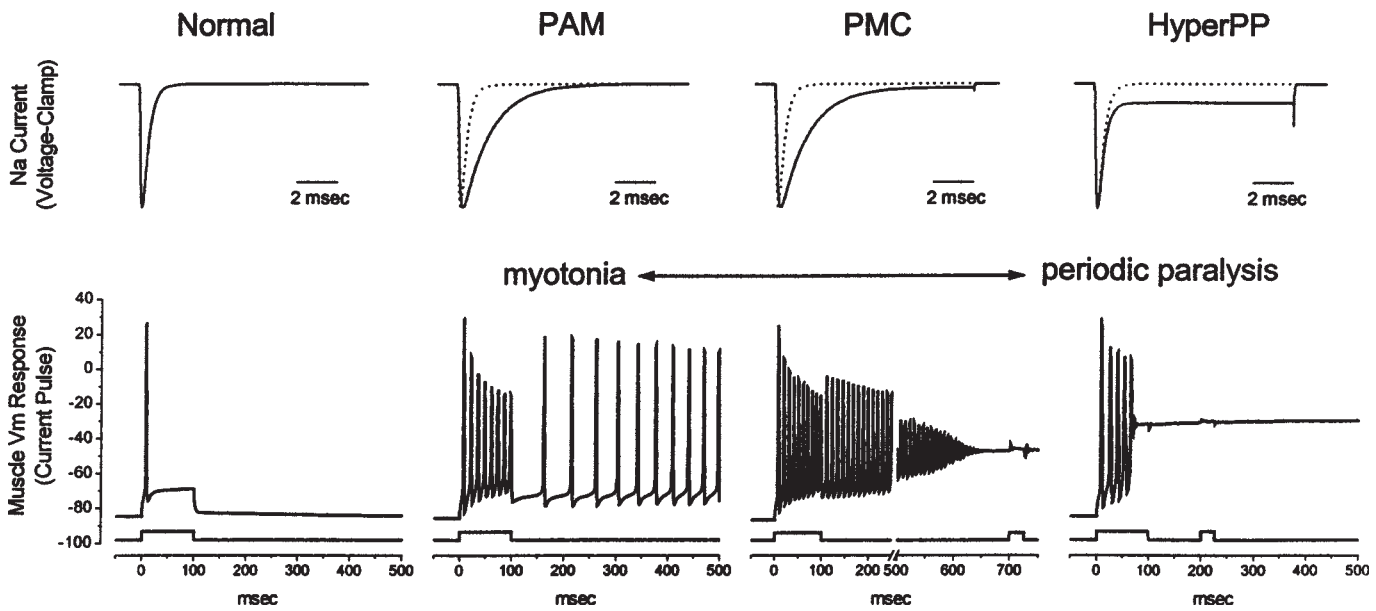

Figure 113-1 Sodium channel gain-of-function defects produce myotonia, periodic paralysis, or a combination of both symptoms. Top row shows currents typical of normal, PAM, PMC, and HyperPP mutant sodium channels. Responses are computer simulations of sodium currents elicited by a 10 ms depolarization from –90 to –110 mV. Superimposed dashed tracings show a comparison of normal to mutant responses. Lower row shows the effects of altered sodium currents on the electrical behavior of a simulated muscle fiber. (Note the difference in time-scale between the top and bottom rows of tracings.) The initial stimulus in each trial is a 100 ms current injection at an intensity of 1.5X threshold (25 $\mu A/cm^2$). Normal muscle responds with a single action potential, and a return to the resting potential after the stimulus is terminated. Mutant sodium channels that slow the rate of inactivation, as in PAM, cause bursts of myotonic discharges that persist even after the stimulus. A small additional sodium channel defect that prevents complete inactivation (2.5% failure) increases the susceptibility to prolonged burst of myotonia followed by sustained depolarization that renders the fiber refractory to a second current pulse (PMC), thereby resulting in paralysis. A modest disruption in the completeness of inactivation alone (5% failure rate) predisposes the fiber to depolarization-induced periodic paralysis, after only a few myotonic discharges, as occurs in HyperPP.

suppression of the chloride current at the resting potential of –90 mV for skeletal muscle.

Potassium Aggravated Myotonia, Paramyotonia Congenita, Hyperkalemic Periodic Paralysis, Hypoklalemic Periodic Paralysis: Allelic Disorders of The Sodium Channel Several allelic disorders of muscle excitability are caused by missense mutations of SCN4A, the gene coding for the adult isoform of the skeletal muscle sodium channel α-subunit. The initial discovery has its origins in the electrophysiological characterization of affected muscle. Some dominant muscle diseases cause both myotonia (enhanced excitability) and periodic paralysis (loss of excitability) in the same patient. The predominant symptom in paramyotonia congenita (PMC) is myotonia that paradoxically worsens with repeated effort (paramyotonia) and is exacerbated by muscle cooling. Patients with PMC may also develop full-blown attacks of periodic paralysis, spontaneously or after extreme cooling. In hyperkalemic periodic paralysis (HyperPP), periodic paralysis in association with an ictal elevation in serum K^+ (>6 mEq/L) predominates, but patients may also have myotonic stiffness. Initial experiments were directed at testing the hypothesis that the chloride conductance would be reduced in these variants of myotonia, as had been established for MC. The chloride conductance was normal, but affected muscle was susceptible to sustained depolarized shifts in the resting potential that rendered the fiber inexcitable from inactivation of sodium channels. This aberrant depolarization was blocked by tetrodotoxin, a potent and specific blocker of the voltage-gated sodium channel. Based on this lead, SCN4A was screened as a candidate disease gene and 30 missense mutations have been identified in families with HyperPP, PMC and two related disorders: potassium aggravated myotonia (PAM) and hypokalemic periodic paralysis (HypoPP). PAM is clinically similar to autosomal-dominant MC, except the myotonia tends to fluctuate more, and ingestion of K^+- rich foods aggravate the myotonia. Periodic paralysis does not occur in PAM. HypoPP presents with recurrent attacks of periodic paralysis and hypokalemia (<3 mEq/L), with onset around puberty and no myotonia. The SCN4A gene is a minor locus for HypoPP, accounting for about 10% of cases, whereas most are resulting from missense mutations in the L-type Ca channel (*see* Hypokalemic Periodic Paralysis).

How does the allelic heterogeneity arise from missense mutations in the skeletal muscle sodium channel? Expression studies have identified differences in the functional effects of mutations associated with a particular phenotype (Fig. 113-1). The clearest distinction is for mutations that segregate along the spectrum from PAM to PMC to HyperPP (pure myotonic, to mixed, to predominantly paralytic). All mutations with these disorders cause gain-of-function defects; mutant channels allow more inward sodium current than occurs in wild-type channels. Most defects arise from to disruption of sodium channel inactivation that normally initiates the repolarization process at the peak of the action potential and is also responsible for the reduced excitability during the refractory period. Susceptibility to myotonia is produced by mutations that slow the time-course of inactivation, thereby leaving an abnormally large pool of available (not inactivated) sodium channels that may generate another action potential at the tail end of the repolarization phase from the first impulse. This is the most common defect in

PAM and PMC mutants. Other mutations disrupt the completeness of sodium channel inactivation. This anomaly creates the possibility of a persistent inward sodium current that would keep the membrane chronically depolarized. When present to a moderate degree (mutant channels fail to inactivate 1–3% of the time), this defect produces a mixed phenotype of myotonia and periodic paralysis as in PMC. Modest depolarization brings the fiber to threshold for spike generation (myotonia), whereas larger depolarized shifts render the fiber inexcitable because of inactivation of the majority of sodium channels are inactivated (both channels from the normal allele and most of the mutant ones as well). Thus, mutant channels exert a dominant negative influence through an effect on membrane voltage; depolarization shuts off normal sodium channels. The depolarized shifts in Vm and attacks of weakness last hours, and so must result from changes in the steady-state behavior of mutant channels, such as the persistent current. Mutations with less complete inactivation (larger persistent sodium currents) or additional defects in slow inactivation (a separate mechanism for blocking current flow in depolarized sodium channels), or enhanced opening for even mild depolarization all predispose the fiber to attacks of depolarization induced periodic paralysis and occur commonly in HyperPP mutations.

The functional defect in HypoPP-associated mutant sodium channels appears to be an enhancement of inactivation. Such a defect would account for the lack of myotonia in HypoPP, but the mechanism(s) whereby affected muscle is aberrantly depolarized to –50 mV during an attack and K^+ shifts into the myoplasm to produce hypokalemia remain to be elucidated.

Hypokalemic Periodic Paralysis HypoPP is the most common form of familial periodic paralysis, but it is still a rare disease with an estimated prevalence of 1/100,000. Distinguishing features of HypoPP are onset at puberty, provocation of attacks by exercise or fasting, absence of myotonia, and ictal hypokalemia. There is no known mechanistic association between familial HypoPP and the sporadic periodic paralysis of hyperthyroidism, which also typically occurs in the setting of hypokalemia. The proximal cause of muscle inexcitability in HypoPP is aberrant persistent depolarization, just as occurs in HyperPP. Despite this dramatic physiological defect, electrophysiological studies on biopsied muscle have failed to identify a consistent defect in a specific ionic conductance. Reductions in an ATP-dependent potassium conductance, or an inward rectifying, potassium current have been reported, as well as a decrease in sodium current density.

The major locus for HypoPP was mapped to chromosome 1q21-31, and screening of candidate ion-channel genes in this region has identified three missense mutations in CACNA1S, the α_{1S}-subunit of the L-type Ca channel in skeletal muscle. Intriguingly, all three defects are missense mutations in positively charged arginine residues thought to form part of the voltage-sensing apparatus of the channel. Functional studies have been hampered by the poor expression of skeletal muscle L-type Ca channels outside the native muscle environment. The available data suggest a loss-of-function defect, with reduced current density and a slowing in the rate of channel activation. These changes do not readily lead to a suggested pathomechanism. Another uncertainty is whether the primary defect is "electrical" resulting from a change in current carried by Ca^{2+} ions or "chemical" resulting from a disruption of a signaling pathway modulated by Ca^{2+} entry through L-type channels.

About 30% of patients with typical clinical features of HypoPP have no identified mutation in CACNA1S. Of these, one-third or 10% of all HypoPP patients have missense mutations of the skeletal muscle sodium channel gene, SCN4A. As described, the sodium channel mutations associated with HypoPP are loss-of-function, because of enhancement of inactivation.

Andersen's Syndrome: Potassium Channel Defect in Heart, Skeletal Muscle, and Bone Andersen's syndrome (AS) is defined by the triad of periodic paralysis, dysmorphic features, and ventricular arrhythmia. Inheritance is dominant, but the penetrance is highly variable and within one family affected individuals might have one, two, or all three features of AS. Episodes of periodic paralysis are usually similar to those in HypoPP, but occasional instances of ictal hyperkalemia have been reported. Unlike all other forms of familial periodic paralysis, AS affects tissues other than skeletal muscle. Dysmorphic features most often affect the face with low-set ears, widely spaced eyes (hypertelorism), and small chin (micrognathia). Abnormal curvature of the fingers and toes (clinodactyly) is also common. Cardiac arrhythmias are varied and include long-QT syndrome, ventricular ectopy, and ventricular tachycardia.

The disease gene in AS was identified by genetic linkage and positional cloning as KCNJ2, which is an intronless gene coding for an inwardly rectifying potassium channel, Kir2.1. Several missense mutations and two in-frame deletions of KCNJ2 have been identified in AS families. KCNJ2 is strongly expressed in heart and brain, as well as muscle, which accounts for disease involvement of tissues other than skeletal muscle. Potassium channels of the inward rectifier type are thought to play a major role is setting the resting Vm. Kir2.1 is one of many inward rectifiers in the Kir2.x family that are expressed in skeletal muscle and combine as tetramers to form the channel complex. The AS mutations produce dominant-negative loss-of-function defects. Mutant channels alone do not form functional channels, and coexpression with wild-type subunits results in a lower current density than is observed when wild-type subunits alone are expressed. A reduction in the net inward rectifying potassium current could account for the depolarization-induced attacks of periodic paralysis and the cardiac repolarization defects that predispose to ventricular arrhythmia. Targeted disruption of KCNJ2 in homozygous knockout mice results in neonatal lethality because of aspiration and asphyxia from a severe cleft palate, thereby establishing a precedent for the importance of this channel in skeletal development, which may account for the dysmorphic features of AS.

CHANNELOPATHIES OF THE CENTRAL NERVOUS SYSTEM

Channelopathies of the CNS are usually manifest clinically as paroxysmal syndromes of transient neurological dysfunction: seizures, hemiplegic migraine, or episodic ataxia (EA). A notable exception is the slowly progressive spinocerebellar ataxia (SCA) associated with mutations in the α_1-subunit of the P/Q-type Ca channel (CACNA1A). The CNS channelopathies may produce considerable phenotypic heterogeneity. For example, mutations in a single Ca channel gene (CACNA1A) may result in EA type-2 (EA2), familial hemiplegic migraine (FHM), or SCA type 6 (SCA6). Conversely, genetic heterogeneity has been observed for several idiopathic epilepsies. Generalized epilepsy with febrile seizures plus (GEFS+) occurs with mutations in three different sodium channel subunit genes or in the γ_2-subunit of the γ-amimobutyric acid receptor type

Table 113-2
Epilepsies Established as Channelopathies of the CNS

Gene	*Channel*	*Syndrome*
CHRNA4	α_4-subunit, nicotinic acetylcholine receptor	ADNFLE
CHRNB2	β_2-subunit, nicotinic acetylcholine receptor	ADNFLE
GABRA1	α_1-subunit, $GABA_A$ receptor	Autosomal-dominant JME
GABRG2	γ_2-subunit, $GABA_A$ receptor	GEFS+/FS/CAE
SCN1A	α-subunit, $Na_V1.1$ sodium channel	GEFS+/intractable childhood epilepsy with generalized tonic–clonic seizures/severe myoclonic epilepsy of infancy
SCN2A	α-subunit, $Na_V1.2$ sodium channel	GEFS+/benign familial neonatal convulsions
SCN1B	β_1-subunit, sodium channel	GEFS+
KCNQ2	KCNQ2 potassium channel	Benign familial neonatal convulsions
KCNQ3	KCNQ3 potassium channel	Benign familial neonatal convulsions
CLCN2	ClC-2 voltage-gated chloride channel	CAE/juvenile absence epilepsy/JME/epilepsy with grand mal seizures on awakening

A ($GABA_A$) (Table 113-2). The identification of the molecular defect for all of the CNS channelopathies was achieved by linkage analysis followed by positional cloning and mutational analysis of candidate genes.

EPILEPSY Idiopathic generalized epilepsy (IGE), defined as epilepsy of unknown cause and the absence of associated neurological features, is presumed to have a genetic basis. In the last decade, ten ion-channel genes have been implicated in monogenic IGE syndromes (*see* Table 113-2). The mutations have been identified in fast ligand-gated (ionotropic) channels (nicotinic AChR, $GABA_A$), and voltage-gated ion channels (sodium channel, M-type potassium channel, chloride channel).

Sodium Channel Epilepsies Neuronal voltage-gated sodium channels are heterotrimeric complexes of the main pore-forming α-subunit, an accessory β_1 (or possibly β_3) and covalently linked β_2-subunits. Sodium channels are closed in resting cells and generate the action potential by opening rapidly as threshold is approached and thereby conducting inward sodium current that strongly depolarizes the cell. Sodium channels inactivate once depolarized, which allows the more slowly activating potassium channels to repolarize the cell and also produces the refractory period wherein sodium channels must recover from inactivation to enable the generation of subsequent action potentials.

Three sodium channel genes (SCN1A, SCN2A, and SCN1B) have been associated with idiopathic epilepsy syndromes. The pore-forming α-subunit genes (SCN1A and SCN2A) and accessory β_1-subunit gene (SCN1B) are expressed throughout the brain, with the SCN1A channels localized to neuronal cell bodies and SCN2A being axonal. Mutations in all three of these sodium channel genes are established causes of GEFS+. GEFS+ is a common epilepsy syndrome of childhood, which encompasses a wide range of seizure types and phenotypic variability within families. The most common presentation is febrile seizures (FS) "plus," where the + indicates that generalized tonic–clonic seizures may also occur without fever or after the age of 6 yr, in distinction from classic FS. The inheritance pattern in GEFS+ is autosomal-dominant, but segregation analysis and phenotypic variability suggests interactions with additional modifying genes in most pedigrees. Based on a few index GEFS+ families with monogenic autosomal-dominant inheritance, missense mutations were identified in SCN1A, SCN2A, and SCN1B. In subsequent studies, these sodium channel subunits were screened as candidate disease genes in additional GEFS+ pedigrees and other familial epilepsies with FS (severe myoclonic epilepsy of infancy, SMEI, and intractable childhood epilepsy with generalized tonic–clonic seizures, ICEGTC). Defects in SCN1A are the most common known genetic cause of familial epilepsy, with over 150 reported mutations. Nearly 80% of families with SEMI or ICEGTC have known mutations in SCN1A and most are catastrophic, with nonsense mutations, frameshift and premature stops.

Expression studies of mutant sodium channels suggest a common gain-of-function defect underlies GEFS+. Inactivation is impaired, as demonstrated by small persistent sodium currents during maintained depolarization (SCN1A mutants), a slower rate of inactivation (SCN2A mutants), or a shift in the voltage dependence of inactivation toward more positive potentials (SCN2A mutant). All of these inactivation defects are predicted to aberrantly depolarize the cell and thereby enhance excitability. In theory, antiepileptic drugs that work by preferentially blocking depolarized sodium channels, such as phenytoin, carbamazepine, or valproate, are predicted to be especially efficacious in preventing seizures produced by this pathomechanism. Improvement with valproate has been reported, but controlled pharmacogenetic studies are not available.

Most mutations of SCN1A associated with the more severe SMEI phenotype are predicted to result in nonfunctional channels, because of nonsense mutations or frameshift mutations with premature stop codons. This observation led to the hypothesis that SCN1A haploinsufficieny resulting from a nonfunctional allele predisposes to SMEI whereas gain-of-function defects resulting from missense mutations cause GEFS+. The pathomechanism may not be so straightforward, because many missense mutations in SCN1A have subsequently been found in SMEI families. A targeted disruption of SCN1A in mice has not been done, so it remains to be tested whether haploinsufficiency in +/– SCN1A knockout mice will produce epilepsy.

Potassium Channel Epilepsies Two potassium channel genes, KCNQ2 and KCNQ3, have been implicated in familial epilepsy. The KCNQ channels are members of the six-transmembrane voltage-dependent family of potassium channels. KCNQ2 and KCNQ3 subunits are highly homologous and co-assemble to form a heterotetrameric potassium channel, which recapitulates the properties of the so-called M-current first identified in sympathetic neurons. The M-current is a subthreshold potassium current that exerts a strong inhibitory influence on neuronal excitability and in turn is inhibited by G-protein coupled receptors,

such as the muscarinic AChR, from which the name M-current is derived.

The initial cloning and characterization of KCNQ2 and KCNQ3 was a direct result of linkage analysis and positional cloning to identify disease genes in benign familial neonatal convulsions (BFNC). BFNC is a rare syndrome of autosomal-dominant inherited multifocal or tonic–clonic seizures that begin within the first few days to months of life. The prognosis is good, with seizures spontaneously disappearing after weeks to months. BFNC was one of the first idiopathic epilepsies to be linked to a candidate region (20q13.3, reported in 1989), and a second minor locus was discovered 4 yr later at 8q24. Characterization of cDNAs from these regions led to the discovery of two new postassium channel genes that were most similar to the cardiac potassium channel responsible for the long-QT syndrome, and thereby became the second and third members of this subfamily, KCNQ2 and KCNQ3. Over a dozen mutations in KCNQ2 and a handful in KCNQ3 have been isolated in BFNC families. Missense mutations are concentrated in the pore-loop between the fifth and sixth transmembrane segments and as frameshift or truncation defects that occur in the long cytoplasmic carboxyl tail, which is thought to be important in directing subunit assembly. Expression studies have shown homomeric mutant channels are nonfunctional. Coexpression of mutant and wild-type channels, to mimic the heterozygous state in patients, results in about 50% reduction in current density consistent with haploinsufficiency rather than a dominant negative effect. The relatively mild effect of haploinsufficiency, as compared with some deleterious alteration in gating, may explain the benign course of BFNC. A reduction in the M-current is expected to increase neuronal excitability, but the mechanism whereby convulsions are limited to the first months of life is unknown. One proposal is that the immature brain has an increased susceptibility to seizures. Alternatively, another potassium channel may be expressed later in life that replaces or compensates for the reduced M-current.

Genetic heterogeneity beyond the KCNQ family has been established for BFNC. Missense mutations in the SCN2A sodium channel have been identified in two families with a BFNC-like syndrome, albeit with somewhat later onset of 4–8 mo.

Chloride Channel Epilepsies Several of the more common forms of IGE were recently mapped to 3q26. A voltage-gated chloride channel at this locus, CLCN2, was screened as a candidate disease gene in 46 IGE families. Mutations were identified in three families: one with an insertion leading to frameshift and premature stop, one with an 11-base deletion, and a third with a missense mutation. The IGE seizure phenotypes were varied within each family and included childhood absence epilepsy (CAE), juvenile absence epilepsy, juvenile myoclonic epilepsy (JME), and epilepsy with grand mal seizures on awakening. Expression studies showed the deletion and insertion mutations were nonfunctional and had a dominant negative effect when coexpressed with wild-type channels. In neurons responsive to GABA, the ClC-2 channel is thought to be an important efflux pathway for chloride ions. A rise in intracellular chloride because of reduced ClC-2 activity would depolarize the reversal potential for $GABA_A$ channels, and may thereby produce seizures by converting the response at $GABA_A$ synapses from inhibitory to excitatory.

$GABA_A$ Receptor Epilepsies GABA is the major inhibitory neurotransmitter in the CNS. The fast ligand-gated $GABA_A$ receptors are pentameric complexes consisting of subunits from up to seven families (α, β, γ, δ, ε, π, θ), although most receptors are thought to be $\alpha\beta\gamma$- or $\alpha\beta\delta$-isoforms. Epilepsy-associated mutations in $GABA_A$ receptors were found first in GABRG2, which codes for the γ_2-subunit. Missense mutations were identified in families with GEFS+ and CAE. Expression studies in $\alpha_1\beta_2\gamma_2$-channels showed loss-of-function changes, either faster deactivation or reduced expression level. More severe mutations in GABRG2 that produced nonfunctional channels because of frameshift/truncation mutations or splice defects were found in families with GEFS+ and SMEI, or with CAE and FS. Mutation of a second $GABA_A$ receptor gene, GABRA1 encoding the α_1-subunit, was identified in a family with autosomal-dominant JME. The missense mutation caused a loss-of-function defect with reduced current amplitude and a 150-fold reduction in sensitivity to GABA. A reduction of inhibitory synaptic activity for mutant $GABA_A$ receptors is expected to predispose to hyperexcitability and epilepsy, but the mechanisms by which distinct seizure phenotypes arise from mutations in the same gene (allelic heterogeneity) remain to be determined.

Acetylcholine Receptor Epilepsies Neuronal nicotinic AChRs are heteropentameric complexes of α- and β-subunits. Numerous isoforms of α- and β-subunit genes have been identified with the predominantly expressed isoforms in brain being α_4 and β_2. Missense mutations in either the α_4 (CHRNA4) or β_2 (CHNRB2) subunits have been identified in families with autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE). The mutations are clustered in the second transmembrane segment, which lines the ion-conducting pore of the channel. Seizures occur most often during sleep onset, often in clusters of spells, with an onset in the first or second decade of life. Electroencephalographic studies show a frontal localization of the seizure focus. Expression studies have revealed mixed effects of the mutations on channel function. A loss-of-function is implicated by reduced single-channel conductance, drastically reduced permeability to Ca^{2+}, and augmented desensitization. Conversely, other mutants increased the sensitivity to agonists and impaired desensitization. The pathogenic basis of seizures in ADNFLE remains to be elucidated. The cholinergic system has been implicated in sleep, which may be a factor in the nocturnal occurrence of seizures. The mechanism whereby the seizure focus is localized to the frontal lobe is unclear, because α_4- and β_2-subunits are expressed diffusively throughout the CNS.

EPISODIC ATAXIA TYPE 1 EA is a rare autosomal-dominant neurological disorder, which presents with recurrent attacks of generalized ataxia that may affect the limbs, trunk, speech, and eye movements. Attacks last for minutes to hours and are triggered by emotional or physical stress. The carbonic anhydrase inhibitor, acetazolamide, is effective at reducing attack frequency and severity. Two forms of EA were distinguished clinically and mapped genetically to different loci. The distinguishing feature of EA Type 1 (EA1) is a coincident interictal rippling of muscles because of spontaneous discharges of the distal motor neuron (neuromyotonia). EA1 maps to chromosome 12p, and screening of a candidate potassium channel gene, KCNA1 encoding the voltage-dependent potassium channel KV1.1, has revealed over ten missense mutations and one premature stop in the cytoplasmic carboxyl terminus. Expression studies have shown mixed effects. Loss-of-function was demonstrated by dominant negative suppression of potassium current density, haploinsufficiency, or accelerated kinetics of deactivation on hyperpolarization. Conversely, other mutations

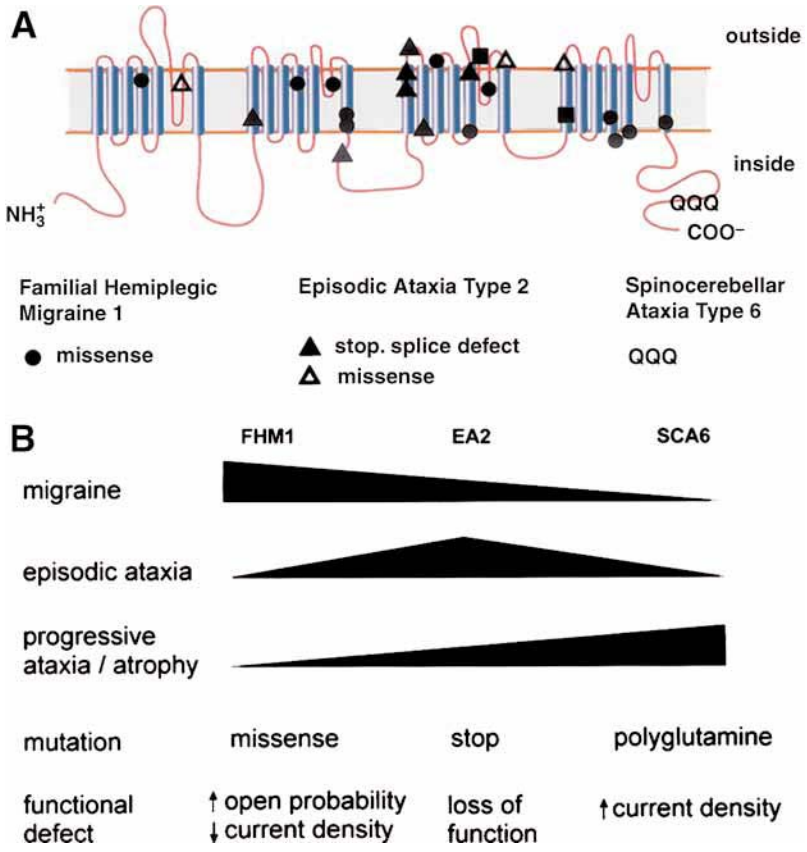

Figure 113-2 Allelic disorders from mutations of CACNA1A encoding the α_1-subunit of the P/Q-type Ca channel. **(A)** Location and type of mutations are shown on the schematic representation of the membrane folding pattern for the P/Q-type α_1-subunit. Filled circles show missense mutations in FHM1. Triangles show position of truncations because of stop/splice errors (filled) or missense mutations found in EA2. Site of the polyglutamine expansion associated with SCA6 is indicated by the symbol QQQ. **(B)** Spectrum of molecular defects, clinical features and disease severity for FHM1, EA2 and SCA6.

slowed the rate of inactivation or accelerated the rate of recovery, both of which imply a gain-of-function defect. Neuronal firing patterns are very sensitive to small changes in potassium currents at subthreshold voltages, and so it is likely that either gain- or loss-of-function defects could be deleterious to neuronal activity. Partial epilepsy has been observed in several EA1 families with known mutations in KCNA1, suggesting that alterations in the Kv1.1 potassium channel may also increase the susceptibility to partial seizures.

FHM, EA2, AND SCA6: ALLELIC DISORDERS OF THE P/Q CA CHANNEL Migraine is a common neurological disorder, characterized by recurrent disabling headache that is typically unilateral with involvement of retroorbital or fronto-temporal regions and associated with vomiting, photophobia and general malaise. Family and population-based studies have suggested a genetic component to migraine, most likely as a polygenic multifactorial mechanism. FHM is a rare autosomal-dominant form of migraine that presents as migraine with aura plus ictal hemiparesis. The trait maps to chromosome 19p13 in about 50% of families, and patients with this so-called FHM1 often develop late-onset cerebellar atrophy. A second locus is at chromosome 1q23, where loss-of-function mutations in the α_2-subunit of the Na^+/K^+ pump produce FMH2. Another autosomal-dominant neurological disorder, EA2, also maps to chromosome 19p13. Like EA1, the predominant feature of EA2 is recurrent attacks of ataxia and dysarthria that are alleviated by the carbonic anhydrase inhibitor acetazolamide. The episodes of ataxia in EA-2 tend to be longer (hours), and there is associated interictal nystagmus, cerebellar atrophy, and increased propensity for migraine.

A candidate disease gene encoding the pore-forming α_1-subunit a P/Q-type Ca channel, CACNA1A, was identified by exon trapping at19p13. This initial report identified four missense mutations in CACNA1A associated with FMH1 and two mutations disrupting the reading frame in families with EA2 (deletion and splice error). Subsequently, a total of 14 missense mutations have been identified in FHM1 families, with the threonine to methionine substitution in the pore region at position or T666M being the most common. The majority of EA2 mutations are predicted to result in a nonfunctional subunit resulting from frame shift–truncation mutations or splice site errors. In a few families with EA-2, missense mutations in CACNA1A have been detected.

A third class of genetic lesion, expansion of a CAG repeat, has been identified in the CACNA1A gene in SCA6. Autosomal-dominant cerebellar ataxia has been recognized clinically for more than a century, and subclasses were first distinguished clinically on the basis of age of onset, severity, or associated degeneration of specific neuronal populations. Subsequently more than 14 different SCAs have been delineated genetically. SCA6 has a late onset in the third or fourth decade with mildly progressive ataxia of limbs and eye movements, and cerebellar atrophy without other

regions of tissue loss by MRI. The CAG polymorphism is in a variably spliced region of the carboxyl cytoplasmic tail of the P/Q-type Ca channel. The normal allele has 4–18 repeats, whereas repeats of 21–33 in number cause SCA6.

The genotype-phenotype correlations observed in these allelic disorders has led to the proposal that increasing severity of the molecular lesion in CACNA1A (missense, nonsense/truncation, and CAG expansion) results in a spectrum of increasingly severe clinical phenotype: FHM1, EA-2, SCA6, respectively, as depicted in Fig. 113-2. CACNA1A is expressed diffusely in the nervous system, and P/Q-type Ca channels are located both presynaptically at the vesicle release site and on neuronal soma and dendrites. Targeted disruption of the CACNA1A homolog in mice causes severe ataxia and dystonia with cerebellar atrophy. Numerous alterations in channel function have been reported in expression studies of α1A-mutants. A common defect for the missense mutations that cause FHM1 is a shift in the voltage dependence of opening, such that mutant channels open more readily for mild depolarization from the resting potential. Other effects are more variable and include decreased density of functional channels, reduced flow of Ca^{2+} through the open channel, and altered kinetics of inactivation. In principle, such varied effects could produce either loss- or gain-of-function changes (i.e., too much or too little Ca^{2+} entry). These alterations in Ca^{2+} signaling and therefore of transmitter release are proposed to underlie the cortical spreading depression responsible for local transient neuronal dysfunction that manifest as the aura of migraine. The majority of EA2 mutations result in truncations because of frame shifts and premature stop codons or splicing defects that are not expected to code for functional subunits. A few missense mutations have been reported in EA2 families, and expression testing of one (F1491S) has shown a complete loss of P/Q-type Ca channel activity. The CAG repeat expansion in SCA6 codes for a polyglutamine track in the cytoplasmic carboxyl tail of the α1A-subunit. The consensus on the effect of this expansion is a gain-of-function change either through increased functional protein levels, a hyperpolarized shift of activation or slower inactivation. The CACNA1A splice variant that includes the polyglutamine track is expressed at high levels in the cerebellum, especially in Purkinje cells, and may explain the selective vulnerability resulting from Ca^{2+} overload.

HYPEREKPLEXIA Hereditary startle disease, or hyperekplexia, is a rare familial disorder with autosomal-dominant or autosomal-recessive inheritance. The core features are an enhanced startle response to environmental stimuli (especially auditory or tactile) often followed by sustained stiffness, nocturnal myoclonus, and neonatal hypertonia. Mutations in the α_1-subunit of the glycine receptor (GLRA1) have been identified in both familial and sporadic hyperkplexia. Glycine receptors are heteropentamers consisting of three α_1- and two β-subunits, and are the major effectors of fast inhibitory neurotransmission in the spinal cord and brainstem. Dominant and recessive missense and nonsense mutations of the α_1-subunit have been reported. Expression studies of mutant channels have shown loss-of-function defects with reduced glycine affinity and a lower conductance of the chloride channel. Interestingly, a transgenic mouse model of a dominant GLRA1 mutation (R271Q) produced a decrease in GABA-ergic inhibitory transmission in the ventral horn of the spinal cord, and diminished glycine receptor transmission. Compound heterozygous mutations in the β_1-subunit (missense and splice mutations of GLRB) have been reported in one boy with transient hyperekplexia. Augmentation of GABA-ergic inhibition with clonazepam alleviates many of the symptoms in hyperekplexia.

114 Charcot-Marie-Tooth Disease and Related Peripheral Neuropathies

JAMES R. LUPSKI

SUMMARY

Molecular genetic analysis of the demyelinating neuropathies Charcot-Marie-Tooth disease and hereditary neuropathy with liability to pressure palsies has uncovered a novel mutational mechanism whereby a reciprocal recombination involving a misaligned flanking repeat sequence results in both the Charcot-Marie-Tooth disease type-1A duplication and hereditary neuropathy with liability to pressure palsies deletion. These studies have illuminated the role that gene dosage may play in causing a disease phenotype, which has important implications for therapeutic strategies, and which may underlie the basis of the extreme clinical variability. The identification of these rearrangement mutations (duplication and deletion) has resulted in the availability of molecular procedures for establishing or excluding a secure diagnosis, enabling presymptomatic and prenatal diagnosis, and providing prognostic information.

Key Words: Charcot-Marie-Tooth disease; congenital hypomyelinating neuropathy; Dejerine-Sottas neuropathy; hereditary neuropathy with liability to pressure palsies; Roussy-Lévy syndrome.

INTRODUCTION

Charcot-Marie-Tooth disease (CMT) is the most common inherited peripheral neuropathy, affecting at least 1 in 2500 individuals. CMT represents a heterogeneous collection of disorders of the peripheral nerve. It can be inherited as an autosomal-dominant, autosomal-recessive, or X-linked trait, and isolated or sporadic cases also occur. The autosomal-dominant segregation pattern is the most frequently observed, and molecular studies identified a novel mutational mechanism for this form—the Charcot-Marie-Tooth disease type 1A (CMT1A) duplication. It is intriguing that for one of the most common dominant disorders affecting humans, no mutant gene is involved in the majority of cases. Instead, the disease phenotype results from having three copies of a normal nonmutated gene or a gene dosage affect secondary to an inherited or *de novo* DNA duplication. Furthermore, an intrinsic structural property of the human genome, a low-copy CMT1A repeat sequence (CMT1A-REP) flanking the duplicated region, acts as a substrate for homologous recombination and an unequal crossover event. This recombination among misaligned flanking CMT1A-REP repeats appears to have a sex predilection and to occur preferentially during male gametogenesis. The identification of the CMT1A duplication has potent implications for clinical diagnosis, clinical management with respect to prognosis, counseling regarding recurrence risk, and the rational design of therapy geared at normalizing the levels of gene expression.

Hereditary neuropathy with liability to pressure palsies (HNPP) (OMIM 162500) is a less frequently diagnosed autosomal-dominant peripheral neuropathy, which usually presents with a milder clinical phenotype than CMT. The patient inherits a tendency to nerve injury after mild trauma; it is likely that many affected individuals remain undiagnosed because they are clinically asymptomatic or only minimally aware of functional disabilities. Carpal tunnel syndrome and other entrapment neuropathies are frequent manifestations of HNPP, making it sometimes difficult to distinguish from an acquired neuropathy. In the majority of cases, HNPP results from DNA deletion of the same genetic region duplicated in CMT1A. Molecular detection of the HNPP deletion secures a diagnosis suspected clinically and can be useful for distinguishing HNPP from acquired neuropathies.

The Dejerine-Sottas neuropathy (DSN) (OMIM 145900) is a rare and severe neuropathy. Though it was initially thought to be an autosomal-recessive trait, molecular studies have identified mutations in only one copy of the two homologues of the same genes that when mutated can lead to a CMT phenotype. These heterozygous mutations presumably represent dominant alleles. However, the DSN phenotype in some cases may result from recessive mutations in select genes (e.g., *PRX* and *GDAP1*). Congenital hypomyelinating neuropathy (CHN) (OMIM 605253) represents the most severe form of hereditary motor and sensory neuropathy (HMSN). The clinical features are present at birth with marked hypotonia, areflexia, and distal muscle weakness. Thus, instead of being completely distinct entities, CHN, DSN, and CMT may more accurately represent a spectrum of related clinical findings owing to allelic heterogeneity underlying the disorders; many CHN and DSN cases may result from new mutant dominant alleles. Roussy-Lévy syndrome (OMIM 180800) combines the CMT1 phenotype with marked tremor and sensory ataxia. It may not be a distinct clinical entity, but rather may represent the spectrum of the CMT1 phenotype.

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

Molecular analyses have identified some thirty genes wherein mutations, or altered dosage of the normal gene in the case of *PMP22*, lead to inherited neuropathies. These genes provide critical reagents to study the biology of peripheral nerves. Each gene product is important for proper structure or function of the Schwann cell, neuron or communication between the two. Molecular genetic studies of CMT and related neuropathies have given new insights into the biology of the human peripheral nervous system and have important implications for patient care.

CLINICAL FEATURES AND PATHOGENESIS

CMT polyneuropathy syndrome, or the HMSNs, are genetically and clinically heterogeneous disorders of the peripheral nerves characterized by an insidious onset and slowly progressive weakness of the distal muscles and mild sensory impairment. Symptoms typically appear in the first or second decade but may appear later. Children with CMT often walk on their toes, and adults consult a physician because of abnormalities of gait from a dropped foot resulting from dorsiflexor weakness, foot deformities such as pes cavus, or loss of balance. Cramps are a frequent complaint, are worse after long walks, and are sometimes exacerbated by cold weather. The most frequent complaint concerning hand function that may occur later in the disease is difficulty with fine finger movements. Deep tendon reflexes disappear early at the ankle and later at the patella and the upper limb.

Electrophysiological and neuropathological studies distinguish two major forms. CMT1 (OMIM 118200), also called HMSNI, is a demyelinating neuropathy with moderately to severely decreased motor nerve conduction velocities (NCVs, usually <38 m/s). The conduction deficit is uniform from nerve to nerve and from nerve segment to nerve segment, suggesting a cell-autonomous defect involving the Schwann cell. CMT1 is characterized by hypertrophic nerves, which may be visualized in some patients under the skin (greater auricular nerve) or palpated (ulnar and peroneal nerves). Peripheral nerve pathology shows segmental demyelination and remyelination and frequent "onion bulb" formation, which consists of circumferentially directed Schwann cells and their processes. CMT has been characterized further with genetic linkage studies, which demonstrate the involvement of over 30 loci. The first three type-1 loci identified include CMT1A at 17p11.2–p12, Charcot-Marie-Tooth disease type 1B (CMT1B) on 1q21.2–q23, and CMTX at Xq13.1.

Charcot-Marie-Tooth disease type 2 (CMT2) (OMIM 118210), also called HMSN type II, is characterized by normal or slightly reduced motor NCVs with decreased amplitudes and neuropathology that shows axonal loss with few if any onion bulbs. DSN (or motor and sensory neuropathy type III) is a demyelinating neuropathy with clinical electrophysiological and histopathological features similar to, but of more severe and earlier onset than CMT1. CHN is at the most severe end of the clinical spectrum with NCVs less than 10 m/s. However, the clinical distinction between CHN and DSN is often difficult. The diagnosis is confirmed by nerve biopsy showing hypomyelination with only a few thin myelin lamellae left without active myelin degradation products and early onion bulb formations. These classifications appear to reflect primary pathological involvement of the myelin (CMT1, DSN, and CHN) or the axon (CMT2) of the peripheral nerve. The clinical distinction of CMT1 vs CMT2 is important both for diagnosis and directing molecular testing. Nevertheless, it has become clear from molecular studies that for some "CMT disease genes" different mutations in the same gene can result in either a type-1 or type-2 CMT phenotype.

HNPP may manifest clinically as periodic episodes of numbness, muscular weakness, atrophy, and in some cases palsies that follow relatively minor compression or trauma to the peripheral nerves. HNPP may present as multifocal neuropathy. Electrophysiological studies sometimes show mildly slowed NCV in clinically affected individuals as well as in asymptomatic "carriers." Conduction blocks can also be observed. Peripheral nerve pathology shows segmental demyelination and remyelination with tomacula or "sausage-like" focal thickenings of the myelin sheath. Ultrastructural studies reveal frequent occurrence of uncompacted myelin, particularly in the inner lamellae, because of separation of the major dense line with widened islands of cytoplasm in the Schwann cell.

MOLECULAR MECHANISMS

DNA DUPLICATION ASSOCIATED WITH CMT1A The CMT1A duplication (OMIM 118220) was identified initially in multiple US and European CMT1 families, wherein it was found to cosegregate with the disease in familial cases and as a new mutation in many isolated or sporadic cases. The segregation of marker genotypes from within the duplicated segment in the new mutation individual suggested a mechanism of unequal crossover or nonsister chromatid exchange for the duplication. Demonstration of the CMT1A duplication in affected individuals was carried out by the following methods: detection of three alleles at a highly polymorphic dinucleotide repeat locus, dosage differences at restriction fragment length polymorphic (RFLP) alleles, detection of a duplication-specific junction fragment of 500 kb with pulsed field gel electrophoresis to separate large-molecular-weight fragments of SacII digested genomic DNA from the affected individual, and microscopically by two-color fluorescent *in situ* hybridization (FISH) of interphase nuclei. Failure to recognize the molecular duplication can lead to misinterpretation of marker genotypes for affected individuals, identification of false recombinants, and incorrect localization of the disease locus. The CMT1A duplication, confirmed subsequently by many laboratories in patients from varied ethnic background, occurs in approx 70% of unrelated CMT1 cases, and was found in 76–90% sporadic CMT1 cases. The junction fragment appeared to be identical in multiple CMT1A duplication patients of varied ethnicity, suggesting a precise recombination event to generate the duplication. Taken together, these observations suggested that the CMT1A duplication was a frequent cause of CMT that appears to have occurred *de novo* multiple and independent times in different genetic backgrounds.

Patients with the CMT1A duplication exhibit typical neuropathology of CMT1. Electrophysiological studies in families segregating the CMT1A duplication demonstrated a clear bimodal distribution of abnormally decreased motor NCV in individuals with the CMT1A duplication, although normal NCVs appeared in those shown not to have inherited the CMT1A duplication. However, a remarkable range of motor NCV was observed in CMT1A duplication patients that were not related to age or clinical severity. Longitudinal electrophysiological studies performed 22 yr apart in one family segregating the CMT1A duplication demonstrated little change in NCV and only mild increased motor impairment. Thus, the CMT1A duplication is a good biological marker for the disease with clinical utility for diagnosis and prognosis.

Molecular studies showed that the duplication was 3 Mb in size, consisting of a tandem arrangement of a 1.5-Mb monomer unit, and that the region duplicated was flanked by an approx 24-kb repeat called CMT1A-REP (Fig. 114-1). Physical mapping studies showed that CMT1A-REP was present in two copies on the normal chromosome as a direct repeat but in three copies on the CMT1A duplication chromosome. Probes to CMT1A-REP were shown to detect specific junction fragments in CMT1A duplication patients. These observations are consistent with a model of unequal crossover whereby misalignment between the proximal copy of CMT1A-REP and the distal copy of CMT1A-REP during meiosis, and a homologous recombination event involving these misaligned repeats, result in the CMT1A duplication. This model predicts a reciprocal recombination that would result in a 1.5-Mb deletion. This latter predicted deletion is responsible for HNPP.

***PMP22* GENE DOSAGE AS A NOVEL MECHANISM FOR CMT1A** Several models were proposed to explain how the CMT1A duplication might alter the expression of a "CMT gene" to result in the disease phenotype. To investigate the gene dosage model, patients with a cytogenetically visible duplication of the short arm of chromosome 17 (17p) underwent electrophysiological studies. Four patients with different cytogenetic duplications had the decreased NCV consistent with CMT1. That these patients had different breakpoints and yet, as long as they duplicated the CMT1A region, they manifested motor NCV abnormalities consistent with CMT1 lends strong support to the gene dosage model even before the identification of a dosage-sensitive gene that maps within the CMT1A duplication.

The identification of the dosage-sensitive gene was aided greatly by concurrent studies on the basic neurobiology of peripheral nerve regeneration and an animal model for CMT1, the Trembler (Tr) mouse. A subtractive hybridization strategy, using cDNA libraries constructed from crushed sciatic nerve vs noncrushed nerve to investigate genes important to nerve regeneration, identified a peripheral myelin-specific gene that was not expressed after crush injury but was expressed at a high level during nerve regeneration and maintenance. This gene mapped to mouse chromosome 11, which is syntenic to human chromosome 17p, encoded a protein of approx 22 kDa, and was called peripheral myelin protein-22, Pmp-22. Pmp-22 was shown to contain a mutation causing different missense amino acid substitutions in the Tr and allelic Tr^J mice. Trembler had been proposed as an animal model for CMT and for DSN based on similar electrophysiological findings of decreased motor NCV and neuropathological findings including onion bulb formation.

The human PMP22 gene was isolated, shown to be expressed at a high level specifically in the peripheral nerve, and mapped within the CMT1A duplication (*see* Fig. 114-1). Subsequently, a human PMP22 missense mutation leading to the identical amino acid substitution identified in Tr^J mouse was found to cosegregate with the CMT1 phenotype in a nonduplication family, whose disease locus was linked to 17p11.2–p12. Similarly, a *de novo* PMP22 mutation was identified in a sporadic nonduplication case of CMT1.

The identification of *de novo* and inherited PMP22 point mutations in DSN further supports the role of PMP22 in demyelinating peripheral neuropathies. These observations, in conjunction with the findings that rare CMT1 patients with smaller or larger duplications each include the PMP22 gene, strongly support the hypothesis that PMP22 is the dosage-sensitive gene in the CMT1A duplication. Further proof for the dosage hypothesis was obtained with the demonstration of elevated PMP22 mRNA expression, and subsequently increased PMP22 protein, in biopsied peripheral nerves from CMT1A duplication patients.

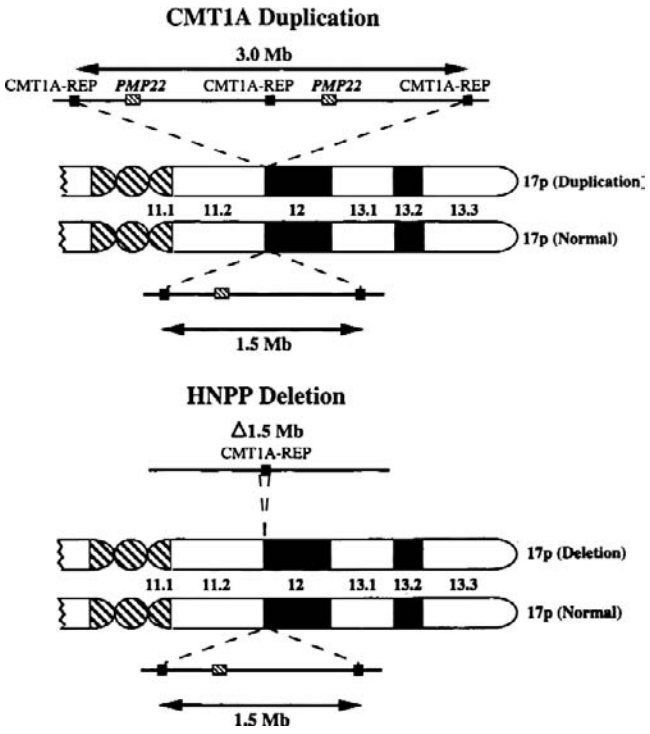

Figure 114-1 Structure of CMT1A duplication and HNPP deletion. The CMT1A duplication is a submicroscopic tandem duplication of a 1.5-Mb DNA region although the HNPP is a 1.5-Mb deletion of the same region in chromosome 17p11.2–p12. The regions on chromosome 17p are depicted, with the normal chromosome shown below and the segmentally duplicated or deleted chromosome above. Crosshatched circles, the centromere. The normal chromosome 17p contains a 1.5-Mb region on the 17p11.2–p12 flanked by homologous CMT1A-REP (filled boxes in blown-up region) of approx 24 kb in length. The *PMP22* gene (crosshatched boxes) maps within this 1.5-Mb critical region, which is duplicated in most patients with CMT and deleted in most patients with HNPP. Genomic sequence analysis reveals that at least 21 genes map within this 1.5-Mb interval. However, observation from patients with either the CMT1A duplication or HNPP deletion suggests that *PMP22* is the only dosage sensitive gene. The 1.5-Mb HNPP deletion is not detected by standard cytogenetic G-banding, and results in deletion of *PMP22* and one copy of CMT1A-REP on one chromosome. CMT1A results from three copies of *PMP22*, although HNPP results from one copy of *PMP22*. The 3.0-Mb CMT1A duplication is not detected cytogenetically, and results in two copies of *PMP22* and three copies of CMT1A-REP on the duplicated chromosomes.

A transgenic rat model of CMT1A and multiple mouse models have been created by overexpression of PMP22. The transgenic rodents recapitulate the CMT phenotype; they develop gait abnormalities, peripheral hypomyelination, onion bulb formation in Schwann cells, and muscle weakness. These models may facilitate the evaluation of potential treatment strategies for CMT1A. Another important animal model is a transgenic mouse constructed by fusing the *Pmp22* gene to a regulatable promoter (that for the tetracycline resistance gene). Overexpression of *Pmp22* results in demyelinating neuropathy. When overexpression of *Pmp22* is switched off in adult mice, correction of the neuropathy begins within 1 wk and

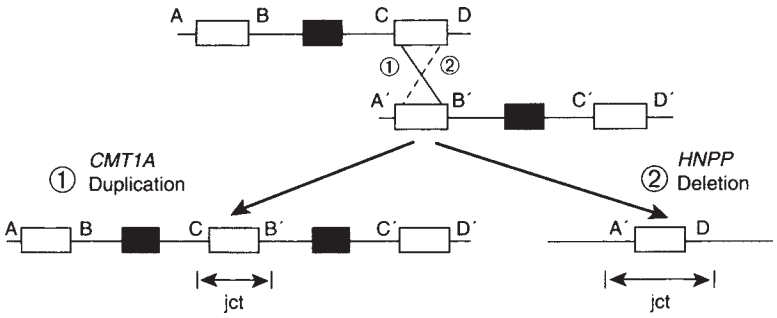

Figure 114-2 Reciprocal recombination resulting from CMT1A or HNPP. Open boxes, CMT1A-REP; solid boxes, *PMP22;* A, B, C, and D, and A′, B′, C′, D′, unique sequences flanking CMT1A-REP on the two chromosome homologs, respectively; circled numbers 1 and 2, the crossovers that lead to the different DNA rearrangements: CMT1A duplication or HNPP deletion; jct, specific junction fragments for the CMT1A duplication and HNPP deletion detected using a CMT1A-REP probe. myelination is well advanced by 3 mo, suggesting that therapy instituted even after the onset of pathology may have a beneficial effect. Recent animal model experiments suggest that normalizing *PMP22* overexpression using small molecules (progesterone antagonist or vitamin C) can provide clinical benefit.

DNA DELETION ASSOCIATED WITH HNPP The HNPP deletion was identified initially in two families segregating autosomal-dominant HNPP and as a *de novo* mutation in a sporadic case. The deletion was demonstrated in affected individuals by loss of RFLP alleles and by FISH. It segregates in a dominant fashion, contains all the markers known to be duplicated in patients with the CMT1A duplication, measures 1.5 Mb in size, and has junctions that overlapped those of the CMT1A duplication (*see* Fig. 114-1). Because the deletion resulted in lack of transmission of deleted alleles to affected offspring, failure to recognize the deletion could lead to erroneous exclusion of paternity or maternity. The PMP22 gene was shown to be deleted in patients with the HNPP deletion. It was proposed as the gene whose underexpression or haploinsufficiency was responsible for HNPP. This hypothesis was substantiated by the subsequent identification of a PMP22 frameshift mutation, leading to a nonsense codon and to a premature termination likely resulting in a null allele, in a nondeletion HNPP family. Additionally, a mouse model with a targeted disruption of *Pmp22* recapitulates the HNPP phenotype including the presence of tomacula or neuropathology.

Although some evidence suggests genetic heterogeneity, most patients appear to have HNPP by the deletion. The identification of similar junction fragments in multiple unrelated families suggests that a precise recombination event is involved in generating the HNPP deletion.

THE CMT1A DUPLICATION AND HNPP DELETION RESULT FROM A RECIPROCAL RECOMBINATION Physical mapping studies of the CMT1A duplication showed that CMT1A-REP was present in three copies on the duplicated chromosome. This finding led to a model for generating the duplication that predicted a reciprocal recombination product of a 1.5-Mb deletion with only one copy of CMT1A-REP remaining on the deleted chromosome. The HNPP deletion was proposed as the anticipated reciprocal recombination product. Molecular analysis in multiple patients detected three copies of CMT1A-REP on both inherited and *de novo* CMT1A duplication chromosomes, and one copy of CMT1A-REP on the deleted chromosome in both inherited and *de novo* HNPP. Furthermore, the predicted HNPP junction fragments with a CMT1A-REP probe were identified. Obviously, these two diseases cannot coexist in the same family lineage because the mutation event must cause duplication and a deletion gamete, only one of which will appear in the fertilized egg and thus be transmitted into subsequent generations. These observations support the hypothesis that a reciprocal recombination mechanism involving CMT1A-REP is responsible for the generation of both the duplicated and deleted chromosomes. Moreover, they document the first examples in humans of Mendelian syndromes resulting from the reciprocal products of unequal exchange involving large intrachromosomal segments, and provide the first example of two distinct human diseases associated with reciprocal products of the same mutational event (Fig. 114-2). Interestingly, there is a recombination hot spot within CMT1A-REP associated with the unequal crossover responsible for the CMT1A duplication and HNPP deletion, and this hot spot is located near a mariner insect transposon-like element.

GENES Approximately 20 genes (Table 114-1), and approx 10 additional loci harboring candidate genes have been associated with CMT and/or related peripheral neuropathies. The phenomenal pace of CMT genes discovery has fomented an unprecedented explosion of information regarding peripheral nerve biology and its pathological manifestations in CMT. The CMT gene discoveries have also led to the availability of molecular diagnostics that enable the establishment of a secure diagnosis, allow calculations of recurrence risk estimates and potentially prenatal diagnosis, and can provide prognostic information. However, limited knowledge is available regarding the relative contribution of the individual genes to the over disease burden, especially for more recently described CMT disease genes. Furthermore, a better appreciation of potential genotype/phenotype correlations requires the examination of many well-characterized patients for specific mutations in specific genes.

In some pediatric neuromuscular clinics and referral centers 40–50% of patients with a peripheral neuropathy have hereditary disease. The inherited peripheral neuropathies constitute a spectrum of neuropathy phenotypes including CMT1 and CMT2, DSN, CHN, and HNPP. Previous advances in identifying specific mutations in various genes have led to extensive genotype/phenotype correlations for selected genes (e.g., *MPZ*), which have confirmed and elucidated further that genetic heterogeneity, age-dependent penetrance, and variable expressivity are key characteristics of the HMSNs. Molecular tools have increased the possibility of establishing a specific etiological diagnosis. However, the expense associated with evaluating multiple genes for disease causing mutations has also escalated.

Table 114-1
Selected Genes in Which Mutations Can Result in CMT or Related Phenotypes

Gene	*Protein*	*Function(s)*	*Disorder(s)*
Cx32	Cx32	Gap-junction formation	CMT1, CMT2
EGR2	EGR2	Transcription factor, cell proliferation	CMT1, CHN, DSN
GARS	GARS	Charging glycyl-tRNA with glycine	CMT2
GDAP1	GDAP1	Neural development/mitochondrial fusion	CMT2, DSN
KIF1B	KIF1B	Motor protein for anterograde transport of mitochondria	CMT2
LMNA	LMNA	Nuclear envelope structure	CMT2
MFN2	MFN2	Mitochondrial fusion	CMT2
MPZ	P_0	Myelin structural protein, homophilic adhesion	CMT1, DSN, CMT2, CHN, RLS
MTMR2	MTMR2	Protein tyrosine dual specificity PI3 phosphatase	CMT1, CHN
NDRG1	NDRG1	Growth arrest/cell differentiation	CMT1
NEFL	NEFL	Neurofilament organization and regulation	CMT2, CMT1, DSN
PMP22	PMP22	Myelin structure/growth arrest	CMT1, HNPP, DSN, CHN, RLS
PRX	PRX	Cytoskeletal, extracellular signaling	DSN, CMT1
RAB7	RAB7	Vesicle transport	CMT2
SBF2	SBF2	Signaling	CMT1
SIMPLE	SIMPLE	Transcription factor	CMT1
			Complex neuropathy
DCTN1	DCTN1	Axonal transport	lower motor neuron disorder without sensory symptoms
GAN1	Gigaxonin	Neurofilament architecture	Giant axonal neuropathy
KCC3	KCC3	K^+Cl^- cotransporter	CMT2 with agenesis of corpus callosum
SOX10	SOX10	Transcription factor essential for neural crest development	CMT1 with Waardenburg Shah
TDP1	TDP1	DNA single-strand break repair	CMT2 with spinocerbellar ataxia

CMT1, CMT2, Charcot-Marie-Tooth types 1 and 2; DSN, Dejerine-Sottas neuropathy; CHN, congenital hypomyelinating neuropathy; RLS, Roussy-Levy syndrome.

Limited genotype/phenotype correlations on previously established CMT disease genes have pointed to some unique features of peripheral neuropathies caused by mutations in specific genes. Some of the more common associations are early upper extremity involvement in *Cx32*, significant sensory signs with *PRX* and *MPZ* mutations, and bulbar involvement or respiratory compromise with *EGR2* mutations. Although these associations are present in only a minority of cases, such unique clinical features can help tailor and focus genetic testing.

Most patients who come to the neuromuscular clinic apparently present with a sporadic disease. However, 40% of these patients can have a hereditary neuropathy. The CMT1A duplication accounts for 52% of all cases of CMT, including 70% of cases of autosomal-dominant CMT1 and 76–90% of cases of "sporadic CMT1." Furthermore, of patients with neuropathy in whom a point mutation of a CMT gene was identified, approx 38% represented *de novo* mutations in sporadic cases. Also, some neuropathies are autosomal-recessive traits that may not have a family history. Hence, molecular genetic testing may potentially be useful in any chronic peripheral neuropathy in which a standard diagnostic workup (for diabetes, uremia, toxins, vitamin deficiencies, paraproteinemias, paraneoplastic syndromes) does not yield a specific diagnosis. As therapeutic modalities develop, specific molecular diagnosis will be a prerequisite to appropriately select patients for clinical trials because most of these treatments will need to be gene and pathophysiology-specific.

PATHOPHYSIOLOGY

About 30 different genes whose proteins appear to perform diverse functions have been associated with a CMT or related neuropathy. In an individual family segregating a CMT or neuropathy phenotype only one specific gene is responsible. In the population of CMT2 neuropathy patients the most important gene (involved in approx 70% of cases) appears to be *PMP22* because duplication, deletion, or point mutation can result in a neuropathy phenotype. For CMT2 patients the most often involved gene appears to be *MFN2* with 20–30% of patients having a point mutation.

Given the many potential genes involved in CMT, the pathophysiology for the disease can potentially be diverse. The genes encode proteins for multiple cellular functions including myelin structure (*MPZ*, *PMP22*) gene transcription (*EGR2*, *SOX10*, *SIMPLE*), signal transduction (*MTMR2*, *SDF2*), and axonal transport (*NEFL*, *KIF1B*, *DCTN1*, *GAN1*) and mitochondrial function (*MFN2*, *GDAP1*) Essentially, it seems that disturbance of a basic cellular process in the neuron, the Schwann cell, or potentially the communication between these two, can lead to a peripheral neuropathy phenotype. The ultimate clinical neuropathy phenotype depends on the gene involved, the type of mutation, and how that mutation affects the protein transport, structure, or function. It is also clear that other genes and the environment may modify the neuropathy phenotype.

Two of the more recently identified genes are of particular interest given their function. *GARS* encode a protein that charges the glycyl-tRNA with gylcine. Unless the possibility exists that this gene encodes a protein with an additional function other than acting as an aminoacyl tRNA synthetase, this observation potentially suggests that proteins rich in the amino acid glycine may be important to axonal function. Interestingly, a mutant tyrosyl-tRNA synthetase has also recently been associated with a CMT phenotype. The *TDP1* gene encodes tyrosyl-DNA phosphodiesterase 1, which repairs covalently bound topoisomerase 1 DNA complexes and is

essential for preventing the formation of double strand breaks that result when stalled topoisomerase 1 complexes interfere with DNA replication. It is a protein important to the single strand break repair pathway. The finding of mutations in this gene in patients that exhibit an axonal neuropathy (CMT2 with spinocerebellar ataxia) suggest that the nervous system is potentially more susceptible to toxic agents that result in DNA single strand breaks.

CLINICAL IMPLICATIONS

MOLECULAR DIAGNOSIS The CMT1A duplication is the causative mutation for the majority of autosomal-dominant CMT1 and occurs as a new mutation in 76–90% of sporadic CMT1 cases. Given its high frequency, the detection of the CMT1A duplication is a useful diagnostic test in patients with inherited as well as sporadic peripheral neuropathy. In a patient with an electrophysiological diagnosis of CMT1, detection of the CMT1A duplication establishes the exact molecular form of the disease in that family. This makes it possible to diagnose or exclude with a simple blood test other family members who are at risk of developing the disease, enables prenatal diagnosis to be offered, and may provide prognostic information.

The HNPP deletion appears to be the causative mutation in the majority of autosomal-dominant and sporadic HNPP cases. HNPP is a milder disease than CMT, and, because the symptoms can be episodic and transient, individuals may be less likely to seek medical attention. It can be a difficult clinical diagnosis to make and requires a high index of suspicion. Therefore, molecular testing can be helpful. The HNPP deletion should be suspected in the following clinical situations: any family showing dominantly inherited pressure palsies, families with multiple members affected with carpal tunnel syndrome or other entrapment neuropathies, and all patients with a recurrent demyelinating mononeuropathy or polyneuropathy of undetermined etiology, because electrophysiological studies can show evidence for conduction block. The detection of the HNPP deletion establishes a precise molecular diagnosis, enables presymptomatic diagnosis in family members at risk, can be useful for prognosis, and will promote preventive measures to avoid nerve pressure or trauma to susceptible areas such as the elbows, wrists, and at the fibular neck of the legs. Although the exact prevalence of HNPP is unknown, sporadic cases should be nearly as common as sporadic CMT1A, because the HNPP deletion and CMT1A duplication represent reciprocal recombination products.

Molecular diagnostic testing is available commercially for the detection of the CMT1A duplication and the HNPP deletion as well as selected neuropathy causing genes in the United States and is performed in molecular diagnostic laboratories throughout the world.

PHENOTYPE/GENOTYPE CORRELATIONS CMT is well-established as a disorder with extreme variability of clinical expression. Some of this variability may have reflected genetic heterogeneity. However, not only there is interfamilial clinical heterogeneity but there is also significant intrafamilial clinical heterogeneity. Families segregating the CMT1A duplication may have substantive variability among affected individuals; the degree of motor NCV decrease can also vary. Clinical variability can even be observed in identical twins with the CMT1A duplication. It has been proposed that this clinical variability may reflect the gene dosage phenomena underlying CMT1A. Patients with the CMT1A duplication have no abnormal gene product, but, instead, their disease reflects abnormally increased expression of *PMP22*. Altered gene expression levels may be more susceptible to modifier gene and/or environmental effects than gene mutations resulting in aberrant proteins.

There is a wide variability of clinical expression for each of the inherited demyelinating neuropathies and clinical diagnostic categories may overlap. Nevertheless, molecular analyses enable some phenotype/genotype correlations as guidelines.

CONCLUSION

Molecular genetic analysis of the demyelinating neuropathies CMT1 and HNPP has uncovered a novel mutational mechanism whereby a reciprocal recombination involving a misaligned flanking repeat sequence results in both the CMT1A duplication and HNPP deletion. These studies have illuminated the role that gene dosage may play in causing a disease phenotype, which has important implications for therapeutic strategies, and which may underlie the basis of the extreme clinical variability. The identification of these rearrangement mutations (duplication and deletion) has resulted in the availability of molecular procedures for establishing or excluding a secure diagnosis, enabling presymptomatic and prenatal diagnosis, and providing prognostic information.

The identification of approx 30 genes wherein structural gene alterations can result in neuropathy phenotypes has led to a better understanding of the molecular basis of CMT and related neuropathies and has provided important tools to investigate further the biology of the peripheral nerve. Multidisciplinary approaches have enabled understanding of the molecular bases for and pathophysiology of the HMSNs. These findings provide a clear focus for efforts to elucidate the cascade of events beginning with a mutation in a gene or altered gene dosage leading ultimately to recognizable diseases phenotypes. This knowledge will be instrumental to the design of rational therapies for these diseases.

115 Amyotrophic Lateral Sclerosis and Related Motor Neuron Disorders

Lessons in Pathogenesis and Therapy From Genetics

ROBERT H. BROWN, JR.

SUMMARY

Amyotrophic lateral sclerosis is a lethal, paralyzing disorder of motor neurons in the brain, brainstem and spinal cord. Its onset, typically in the 6th decade of life, is age-dependent; mean onset is 55 yr, and mean survival is 3–5 yr. About 5–10% of cases are transmitted as an autosomal dominant trait familial amyotrophic lateral sclerosis. This chapter concentrates on lessons from studies of inherited forms of motor neuron disease, including familial amyotrophic lateral sclerosis.

Key Words: Amyotrophic lateral sclerosis; familial amyotrophic lateral sclerosis; familial spastic paraplegia; hereditary; primary lateral sclerosis; sporadic amyotrophic lateral sclerosis; spinal muscular atrophies.

INTRODUCTION

Several lines of investigation have provided fresh insights into the molecular basis for many neurodegenerative disorders. This chapter concentrates on lessons from studies of inherited forms of motor neuron disease, including familial amyotrophic lateral sclerosis (FALS). It emphasizes general principles that may encompass several categories of neurodegenerative disorders. Genetic loci have been described for several types of familial motor neuron disease (Tables 115-1–115-3). Knowledge of the molecular lesions that trigger motor nerve death in FALS improves the understanding of all motor neuron diseases' pathophysiology (both familial and sporadic) and of neurobiological properties of this cell.

DISORDERS OF THE UPPER AND LOWER MOTOR NEURONS

DOMINANTLY INHERITED, ADULT-ONSET AMYOTROPHIC LATERAL SCLEROSIS Amyotrophic lateral sclerosis (ALS) is a lethal, paralyzing disorder of motor neurons in the brain, brainstem, and spinal cord. Its onset, typically in the sixth decade of life, is age-dependent; mean onset is 55 yr, and mean survival is 3–5 yr. About 5–10% of cases are transmitted as an autosomal dominant trait (FALS).

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

When lower motor neurons die, patients develop weakness with muscle wasting. The disease begins insidiously with distal, focal weakness, sometimes accompanied by muscle cramping and spontaneous twitching (fasciculations). When denervation involves bulbar muscles, the complaint is difficulty chewing, swallowing, and speaking. Rarely, ALS presents as primary respiratory failure. When the disorder begins in corticospinal motor neurons, the clinical manifestation is weakness with spasticity. There is no loss of sensory, sphincteric, or cognitive function. The hallmark of ALS at autopsy is atrophy and loss of motor neurons, sometimes with gliosis. ALS motor neurons show cytoskeletal aberrations such as axonal "spheroids," and filamentous aggregations within the cell bodies. The latter may be positive for ubiquitin, sometimes in thread-like "skein" structures.

On clinical and pathological ground, familial ALS (FALS) is indistinguishable from sporadic amyotrophic lateral sclerosis. This strongly suggests that these diseases involve similar pathogenic mechanisms. In a subset of FALS pedigrees, mutations in the gene for cytosolic, copper/zinc superoxide dismutase (SOD1) were identified in a subset of FALS pedigrees. More than 100 SOD1 mutations have been detected in such families. SOD1 is a homodimeric enzyme of 153 amino acids that has been highly conserved during evolution. It is a member of a family of related proteins including a Mn-dependent superoxide dismutase (SOD2) expressed in mitochondria and an extracellular form (Cu/Zn dependent, SOD3). SOD1 catalyzes the conversion of O_2^- to H_2O_2 (Fig. 115-1A). H_2O_2 is then converted to H_2O by catalase or glutathione peroxidase. These facts suggest that free radical toxicity might be implicated when SOD1 is mutated, although this hypothesis remains controversial.

There is a reduction of total brain SOD1 activity in some familial ALS patients with SOD1 mutations but not in sporadic amyotrophic lateral sclerosis patients or FALS patients without SOD1 mutations. Some SOD1 mutations reduce SOD1 activity in red blood cells and lymphoblastoid lines.

Several markers of oxidative injury (to proteins, lipids and DNA) are increased in ALS tissues. These include carbonyl proteins, peroxidated lipids, and oxidatively modified DNA. Moreover, there are also indications that rather striking oxidative markers can be detected in ALS spinal fluid.

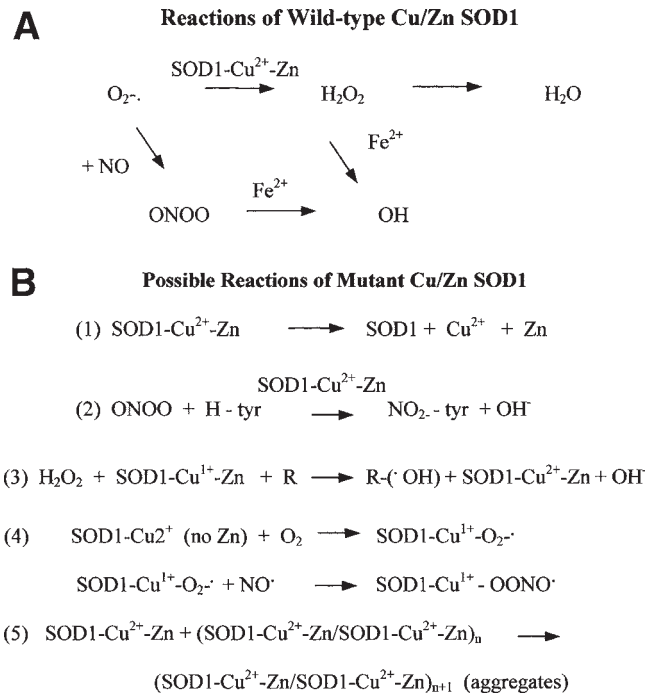

Figure 115-1 **(A)** Selected reactions of cytosolic copper, zinc superoxide dismutase (SOD1). SOD1 catalyzes the conversion (dismutation) of O_2^- to H_2O_2. H_2O_2 is converted to water by catalase and glutathione peroxidase. O_2^- can combine noncatalytically with NO to form ONOO–. ONOO– and H_2O_2 can interact with reduced metals such as Fe^{2+} or Cu^{1+} to hydroxyl radicals. **(B)** Putative reactions of mutant Cu/Zn SOD1. (1) Familial amyotrophic lateral sclerosis (FALS)-associated mutations may lessen the affinity of SOD1 for copper and zinc. (2) Nitronium anions may be formed more rapidly by the reaction of ONOO– with mutant SOD1 in the presence of FALS mutations; this may accelerate transfer of nitrate groups to tyrosines. (3) FALS-associated mutations may favor the reduction of Cu^{2+}, enhancing the ability of SOD1 to reduce substrates like H_2O_2 and thereby act as a peroxidase. (4) In the absence of zinc, oxygen can reduce Cu^{2+} in SOD1 to produce O_2^- within the active channel; this can potentially interact with nitric oxide to form ONOO–. (5) Mutant SOD1 may be unstable and aggregate, both with itself and with wild-type SOD1.

Reports documenting that SOD1 activity is decreased in tissues of patients with SOD1-associated FALS initially raised the possibility that motor neuron death is a direct consequence of this loss of SOD1 function. For example, as reviewed later, studies of motor neurons in vitro show that diminished superoxide activity initiates programmed cell death of neurons. However, several arguments strongly favor the view that the mutant SOD1 protein has acquired properties that are lethal for the motor neuron. Strong support for this view is the observation that SOD1 knock-out mice do not develop motor neuron cell death in the first few months of life. Oppositely, overexpression of FALS-related mutant SOD1 protein (with FALS mutations) causes a lethal, paralytic disorder in mice beginning at 3–5 mo of age, and in rats.

These considerations indicate that the mutant SOD1 molecule is cytotoxic. Although the basis for this novel activity is not yet well established, several possible adverse functions for the mutant molecule have been proposed (Fig. 115-1B). One possibility is that metal binding properties of some mutants (e.g., G85R and G93A) are abnormal, and that either copper or zinc acts as a toxin for motor neurons. It also has been reported that deficiency of zinc from SOD1 enhances its potential toxicity, both in the wild type (WT) and mutant form. Indeed, in neurons in cell culture, zinc-deficient apoprotein is as toxic as the zinc-deficient mutant protein; when fully zinc-loaded, neither form of the protein is toxic in this system. Another hypothesis is that nitration of critical tyrosine residues is a key event. High-pressure liquid chromatography and immunochemical studies indicate that levels of nitrotyrosine are augmented in human and mouse ALS brains. A fourth hypothesis is that the mutant SOD1 protein has an enhanced ability to act as a peroxidase with H_2O_2 as a substrate. This hypothesis is consistent with reports that levels of production of hydroxyl radicals are increased in ALS mice.

Distinct from the foregoing proposals is the alternative suggestion that the critical effect of mutations in this abundant SOD1 protein (up to 0.5% of intracellular proteins) is to cause misfolding, leading to the accumulation of unstable, mutant protein, perhaps as insoluble toxic aggregates. The stability of many of the mutant SOD1 proteins are reduced when expressed in mammalian cells. More recent studies document that the most, if not all, of the mutant SOD1 proteins are unstable either at baseline or with minimal physiological stresses. Such aggregates might be directly injurious; they might also act by impairing normal endogenous mechanisms for protein reutilization. It is proposed that through one or more of these adverse biochemical reactions, the mutant SOD1 protein is directly or indirectly toxic to the cell. Whether oxidative pathology is critical for the cytotoxic effects of mutant SOD1 is unclear. An elegant study documented that elimination in the ALS mice of a protein responsible for loading copper into the active site of SOD1 does not ameliorate the disease; this has been interpreted as excluding a role for copper-mediated oxidative pathology; however, this view has been challenged on the grounds that there may be residual copper associated with the SOD1 molecule either in the normal active site or at an atypical but potentially toxic site.

Several possible targets exist for this toxicity. One intensively studied target is the astroglial glutamate transporter, EAAT2 or GLT1. This protein is strongly implicated as a factor in ALS pathogenesis both because glutamate toxicity has generally been incriminated in the disease and because studies have documented a decrease in both astroglial glutamate transport activity and levels of EAAT2 protein. It has been suggested that the latter might be a consequence of altered splicing of the RNA transcript for EAAT2. Studies show that EAAT2 is susceptible to inactivation by mutant SOD1, particularly in the face of oxidative challenge by H_2O_2 or iron. Another molecular target of mutant SOD1 protein is the voltage-sensitive Na^+ channel, which shows diminished Na^+ current and a depolarizing shift of the voltage dependence of activation in the presence of mutant SOD1. A third important target is the Na^+/K^+ pump; one report documents a marked reduction in subunits of this pump in spinal cords of mice expressing high levels of mutant $SOD1^{G93A}$.

At the level of subcellular organelles, another important target of mutant SOD1 protein are mitochondria. High levels of the protein, as expressed in different lines of transgenic ALS mice, trigger striking morphological changes in mitochondria selectively in motor neurons. It is clear that high levels of both WT and mutant SOD1 are evident in mitochondria. Moreover, mutant SOD1 is apparently more toxic when localized to mitochondria than in other organelles. The mutant SOD1 protein within mitochondria disrupts electron transport and ATP generation at the time of

disease onset but not in presymptomatic stages. The process by which SOD1 enters the mitochondrion is not clear, although this may be enhanced by demetallation; entry of mutant SOD1 into mitochondria is blocked by binding to heat shock proteins, a process that may divert these proteins from critical antiapoptotic functions.

In addition to specific molecules and subcellular organelles, some subcellular processes are deficient in the presence of aberrant SOD1. Important among these is axonal transport, which may decline many weeks before motor neuron degeneration becomes evident. In turn, this diminishes peripheral transport of critical proteins such as tubulin and neurofilaments.

It became apparent from several lines of study that whatever the specific target or mechanism of its action, mutant SOD1 protein can markedly induce activity of cell death genes in neurons. This is particularly remarkable because WT SOD1 is antiapoptotic. The proapoptotic properties of mutant SOD1 were first explored in a variety of cell types in vitro, including yeast cells and diverse types of neuronal cells. In one model, the proapoptotic mutant SOD1 protein aggregates within the cytosol of motor neurons. Oxidative stress can activate the cell death gene caspase-1 (IL-1β converting enzyme) and thereby lead to increased formation and secretion of IL-1β; this change is also seen in the spinal cords of ALS mice. Subsequently, it was shown that both caspase-1 and -3 are activated sequentially in the spinal cords of the $SOD1^{G93A}$ mice. The activation of caspase 3 appears to invoke a pathway of programmed cell death that implicates mitochondria, with increased expression of BAX, release of cytochrome-*c* and activation of caspase 9.

The prediction from these observations that inhibition of caspases might slow the motor neuron disease has been tested in some experiments. Inactivation of caspase 1 slightly prolongs survival in ALS mice bearing the glycine 93 to alanine mutation. Similarly, overexpression of the antiapoptotic protein (NAIP) bcl-2 slows the onset of the disease in these mice. Moreover, infusion of tetrapeptide pan-caspase inhibitors into the spinal fluid of ALS mice prolongs survival by approx 25%. Analogously, treatment with minocycline is also beneficial. These findings are of general interest in understanding cell death in neurodegenerative disorders, as activation of caspase-1 and elevation of IL-1β levels have also been detected in the brains of patients with Huntington's disease.

Non-neuronal cells are abnormal in ALS. There is, for example, intense microglial proliferation and some astrogliosis, in both human and murine ALS. In fact, astroglial proliferation is one of the earliest microscopic changes in murine ALS. Numerous studies have found evidence for activation of inflammatory cascades in spinal cord in transgenic and human ALS. For example, the observation that COX2 is elevated in ALS mice led to studies confirming its elevation in humans with sporadic ALS. One view is that elevated spinal cord COX 2 activity generates elevated levels of prostaglandin that, in turn, enhance glutamate release. In this context, it was of considerable importance that inhibition of COX 2 retarded motor neuron cell death in a Petri dish model of motor neuron degeneration. A subsequent studied showed that COX 2 inhibition prolongs survival in ALS mice. This striking finding has, in turn, led to a multicenter trial of celecoxib in human ALS.

A central issue in understanding the pathogenesis of mutant SOD1-mediated neuronal death is the degree to which it reflects cascades of events evolving selectively within the motor neuron (a cell autonomous death process). The activation of inflammatory cells and molecular cascades suggests that abnormal biological properties of activated non-neuronal cells that surround the motor neuron might contribute to the death of neuronal cells. Three centers published a joint report that demonstrated, using chimeric mice with varying contributions of WT and mutant SOD1-bearing cells, that surprisingly small fractions of WT cells in the spinal cord (e.g., 15–20%) can rescue the motor neuron death phenotype. Particularly striking is that the rescue is not attributable simply to survival of WT motor neurons. Rather, the presence of the WT cells allows the motor neurons bearing mutant SOD1 to avoid cell death. In a chimeric mouse with equal numbers of WT SOD1 and G93A-mutant SOD1 cells, there was no weakness at more than 1 yr of age, whereas the all-mutant G93A-mutant SOD1 transgenic mouse died at 135 d. Moreover, in that chimeric mouse, equal numbers of WT SOD1 and G93A-SOD1 spinal motor neurons were evident at more than 1 yr of age. Also remarkable in these studies was that the presence of mutant-SOD1-positive cells was injurious to WT motor neurons, as assessed by the presence of ubiquitin-positive inclusions.

TREATMENT OF ALS Regrettably, there is no therapy that substantially augments survival in ALS. Riluzole, which is thought to act primarily but not exclusively through inhibition of glutamate, has repeatedly been documented to prolong survival in ALS by approx 10–15%. The availability of mouse and now cell-based models for cytotoxicity by mutant SOD1 protein should accelerate the search for effective therapies. An extensive series of compounds and manipulations have proven statistically if not biologically significant in extending the life span of the ALS mice. A partial list includes the following categories of compounds: antioxidants (vitamin E, buckminsterfullerine, lyophilized red wine, and gingseng root); copper chelating agents (d-penicillamine, trientine, and ascorbate); antiglutamate compounds (riluzole, gabapentin), and agents that augment cellular energy production (coenzyme Q10, creatine). Beneficial genetic approaches to ameliorating the disease in mice have consisted of overexpression of the major astroglial glutamate transporter, EAAT2, and forced expression of two compounds that inhibit apoptosis, bcl-2 and a dominant negative inhibitor of caspase-1. As noted, infusion of tetrapeptide inhibitors of caspases also slowed the course of the disease in the mice. Particularly exciting has been the observation that activity of the enzyme COX2 is elevated in spinal cords of ALS patients and in ALS mice. This has a direct implication for therapy, as potent cyclo-oxygenase inhibitors are already in widespread use in such disorders as arthritis. The observation that the cyclooxygenase inhibition can slow the course of motor neuron disease in ALS mice has led to a multicenter human trial of this drug in ALS.

Several genetic manipulations that alter levels of expression of subunits of neurofilaments in the motor nerve axons have also had significant impact on the survival of the transgenic ALS mice. For example, expression of high levels of the heavy neurofilament subunit (NF-H) increases the lifespan of the G37R mice by approx 65%. Analogously, blocking expression of any axonal neurofilament subunits by knocking out the light neurofilament subunits (NF-L) also prolongs survival. This apparent paradox may be resolved by the observation that in both of these mouse strains neurofilament aggregates accumulate within the soma of the motor neuron. The prediction of this finding is that genetic manipulations that stoichiometrically reduce NF-L, medium neurofilament subunits, and NF-H should reduce axon NF burden (and axonal caliber) without causing NF accumulations in the cell body. If the NF aggregates protect the G37R mice, these mice should have the typical, shorter survival of the unmanipulated

G37R mice. However, if the critical factor is the diminution in axonal NF burden, these mice should have enhanced survival. When this painstaking experiment was completed, it favored the former view. The resulting mice had no accumulation of NF protein in the motor neuron cell body, and they showed no prolongation in survival. Why the aggregated NF protein in the cell body might partially rescue the ALS phenotype is not clear, although studies in progress suggest the accumulated proteins may act as a sink or buffer for one or more adverse substances.

At least two other strategies for treating the ALS mice have been attempted. Gene therapy has been attempted with cautiously encouraging results. Two groups have shown a modest benefit from administration of, glial cell-derived neurotrophic factor, GDNF. When myoblasts transduced with GDNF ex vivo are implanted in the ALS mice, a modest but statistically significant benefit resulted. Intramuscular, segmental administration of GDNF via adenoviral vectors also produced a modest survival benefit in the ALS mice. Dramatic prolongation of survival of the G93A ALS transgenic mice has been afforded by retrograde delivery of insulin-like growth factor-1 via an adeno-associated virus vector.

The other, dramatically different therapy used in the ALS mice was systemic administration of human umbilical cord blood cells. It was reported that intravenous infusion of 30–70 million cord blood cells into ALS mice that have been exposed to near lethal irradiation extends the life of some of the recipients by as much as 50%. A positive but less pronounced benefit was reported in a second study of human umbilical cord blood therapy in the G93A ALS mice.

NON-SOD1, DOMINANTLY INHERITED ALS—THE ROLE OF MOTOR PROTEINS Because most cases of dominantly inherited, adult-onset ALS are not associated with mutations in the SOD1 gene, there is an intense effort to identify the underlying ALS-associated gene defects. In a family with a slowly progressive form of ALS, characterized by vocal cord involvement and prominent bulbar features, a mutation has been identified in the gene encoding the motor protein dynactin. The causative missense mutations are predicted to alter binding microtubules and thereby adversely affect axonal transport. This signal observation was noteworthy for three reasons. First, it is the first evidence for direct involvement of motor abnormalities of motor transport in ALS. Second, that motor proteins are pivotal in the viability of motor neurons is further underscored by the observations that three forms of kinesin are mutated in three forms of motor neuropathy, KIF1Bβ in Charcot-Marie Tooth type 2A, KIF21A in congenital fibrosis of the extraocular muscles because of absence of the superior division of the third nerve, and KIF5A in a form of hereditary spastic paraparesis. Third, almost simultaneously with the report of the dynactin mutation in human motor neuron disease, it was reported that a mouse model of motor neuron disease ("legs at odd angles") is caused by mutations in the gene that expresses dynein, a dynactin binding protein.

DOMINANTLY INHERITED, JUVENILE-ONSET ALS A single large family with a slowly evolving disorder of both upper and lower motor neurons has been mapped to a single a large pedigree with this disease to chromosome 9. The linked locus has been successfully narrowed and studies show that the causative mutation is in the gene encoding the gene for sentaxin, a DNA helicase.

RECESSIVELY INHERITED, JUVENILE-ONSET ALS In recessively inherited juvenile ALS, there is very slowly progressive degeneration of both upper and lower motor neurons and a survival of several decades. This "juvenile ALS" appears to be recessively inherited. Most affected individuals have limb atrophy, reflecting both disuse and some degree of denervation. In two small families, the disease is predominantly because of degeneration of the corticospinal and corticobulbar tracts; these features have suggested this disorder should be designated juvenile primary lateral sclerosis (PLS). In some families, this disorder is mapped to chromosome 2q33; in others the disorder maps to chromosome 15q. The 2q33 locus has been fully cloned; several candidate genes within it have been identified. The gene defect in these families has been attributed to mutations in gene encoding a protein with domains that show homology to guanine nucleotide exchange factors. This gene is therefore thought to regulate activity of one or more GTPases.

DISORDERS OF THE LOWER MOTOR NEURON

SPINAL MUSCULAR ATROPHY The spinal muscular atrophies (SMAs) are characterized by progressive death of lower motor neurons in the brainstem and spinal cord. SMA is inherited as an autosomal recessive trait. Type I SMA (Werdnig-Hoffmann disease) begins very early (and may be evident *in utero* as diminished fetal movement in the weeks before birth). Werdnig-Hoffmann infants are weak, floppy, and suck and cry feebly. They never develop enough strength to sit up and they rarely survive beyond 2 yr. SMA I is relatively common, affecting up to 1/20,000 babies. The carrier frequency for SMA I is 1/80. Type II SMA begins clinically before 18 mo of age but is associated with long-term survival. Unlike SMA I patients, those with SMA II can sit but they cannot stand or walk. Patients with SMA III, which begins after 18 mo, are able to walk. In late-onset SMA (Kugelberg-Welander disease), weakness may be more evident proximally than distally; often the legs are more severely involved than the arms. The hallmark of SMA microscopically is lower motor neurons cell death.

Genetically, all forms of SMA are linked to chromosome 5. The critical gene appears to be a novel protein of 294 amino acids designated the "survival motor neuron" protein or SMN. The locus encoding SMN and NAIP is complex; it is duplicated such that there are at least two copies SMN (telomeric or centromeric). These copies differ only in that one exon (exon 7) is spliced out of the centromeric copy. SMN has been localized both to the nucleus and cytoplasm in cells in vitro. Its function is not entirely clear although several elegant studies have documented that it complexes with several ribonuclear proteins in spliceosomes and may be important in the shuttling of RNA between the nucleus and cytoplasm. The fundamental defect in SMA may involve aberrant splicing and trafficking of mRNA species. The telomeric copy of SMN is deleted in 98% of SMA patients. In the remaining approx 2%, it has undergone gene conversion such that it has the sequence of the centromeric copy of the protein. The severity of SMA is probably modified by several factors including the overall level of expressed SMN, the number of intact copies of SMN_t, and the presence or absence of neighboring genes that are commonly deleted with SMN. These include a NAIP and a second protein even more closely associated with SMN designated 4F5. Mouse models of SMA have been developed. Two entail dual genetic manipulations: knocking out the single native SMN gene in mice (a change that, by itself, is lethal because mice have only one copy of SMN), and expressing a transgenic copy of the human centromeric SMN gene. The third involves a motor neuron specific deletion of exon 7 from the endogenous SMN gene. The phenotype of the resulting animals rather closely resembles SMA.

ADULT-ONSET TAY SACH'S DISEASE Infrequently, patients with G_{M2} gangliosidosis develop a slowly progressive motor neuropathy characterized by lifelong motor clumsiness and later development of frank proximal muscle weakness. These individuals may also manifest some upper motor neuron signs, cerebellar features and behavioral features such as an altered attention span or even psychotic episodes. Bulbar features such as dysphagia and some dysarthria may become apparent. The critical defect in Tay-Sach's disease is an accumulation of G_{M2} ganglioside that develops because of deficiency of activity of the proteins that metabolize G_{M2} ganglioside, *N*-acetyl-hexosaminidase A and B. These dimeric enzymes consist of an α and a β subunit (hexosaminidase A), or two β subunits (hexosaminidase B). Each dimer is complexed with a third protein, G_{M2}activator, which modulates the activity of both enzymes.

X-LINKED SPINAL BULBAR MUSCULAR ATROPHY This is a slowly progressive, familial motor neuropathy that affects only males. In addition to motor weakness, there may be subtle gynecomastia and testicular atrophy, as well as low-grade sensory findings. The molecular defect in X-linked spinal bulbar muscular atrophy (X-SBMA) is an expansion of a CAG repeat in exon 1 of the androgen receptor gene. This produces an expanded polyglutamine tract within the receptor. In general, the longer is the tract of repeated CAGs, the more severe the illness. The mechanism of neurotoxicity of the CAGs is not known, although data suggest that the expanded polyglutamine tract may aggregate to form nuclear inclusions in these CAG-expansion diseases. In neurons in cell culture, expanded polyglutamine tracts induce apoptosis through activation of a specific cell death gene, caspase 8. Data suggest that in X-SBMA and other CAG repeat diseases, accumulation of CREB-binding protein (CRB) in the intranuclear aggregates may be a pivotal element in the pathogenesis of the disease; forced expression of CREB-binding protein can correct the neurotoxicity of the expanded androgen receptor glutamine repeat domain. The availability of transgenic mice with expanded androgen receptor polyglutamine tract should facilitate studies of pathogenesis and therapy of X-SBMA.

DISORDERS OF THE UPPER MOTOR NEURON

PRIMARY LATERAL SCLEROSIS PLS is a disorder that selectively targets the upper motor neuron. It usually occurs as a sporadic disease. Its main clinical feature is slowly progressive weakness without atrophy but with marked limb spasticity. Laboratory studies (electromyography and muscle biopsies) do not detect denervation of muscles. Although long-term survival is reported in PLS, the disease may run its course aggressively with 3–4 yr survival from onset to death. Autopsy shows loss of pyramidal cells in the motor cortex with corresponding degeneration of the corticospinal and corticobulbar projections. Early PLS raises the diagnostic possibility of multiple sclerosis or other demyelinating diseases, although these diagnoses are usually clarified over time.

HEREDITARY FAMILIAL SPASTIC PARAPLEGIA Hereditary familial spastic paraplegia (HSP) is an autosomal dominant trait with a clinical picture marked by spastic weakness beginning in the distal legs. The crucial neuropathological abnormality is corticospinal tract degeneration that is more pronounced caudally. In "complicated" HSP progressive spasticity is accompanied by findings not confined to the corticospinal tract. These include amyotrophy, mental retardation, optic atrophy, and sensory neuropathy; the corresponding pathology is not confined to the corticospinal tracts. In the more common, "uncomplicated" form, HSP is purely a corticospinal disease. Fortunately, genetic studies are illuminating some of these clinical distinctions. At least 10 HSP genes are identified (*see* Table 115-3). An early onset pedigree with spastic gait, relatively little weakness, and a very slow disease course is mapped to chromosome 14q and encodes the protein spastin, whose mutation is implicated in approx 40% of HSP. A large family with uncomplicated HSP has also been linked to chromosome 15q. This family has a more variable age of onset and a more aggressive course than the 14q family. Both early and late-onset families map to a third HSP locus on chromosome 2p. The defective gene at this locus has been identified and termed "spastin;" this protein may play a role in the metabolism of nucleoproteins. Table 115-3 enumerates the other known HSP genes. As described, one involves a gene that encodes a kinesin, further implicating motor protein dysfunction in motor degeneration. Also of interest is the involvement of a possible heat shock protein HSPD1 in another form of HSP. There is extensive genetic heterogeneity in dominantly inherited, uncomplicated HSP. Moreover, other HSP loci remain to be identified.

There are early onset forms of recessively inherited HSP. One locus, on chromosome 16, encodes a novel gene, "paraplegin," whose gene product is thought to function within mitochondria and to have homology to a yeast ATPase. A locus for uncomplicated, recessive HSP has been reported on chromosome 8q. X-linked recessive forms are also reported. One is caused by mutations in the gene encoding proteolipid protein. It is intriguing that other mutations within this gene cause the more fulminant Pelizaeus-Merzbacher disease. Another type of complicated, infantile-onset HSP is caused by mutations in the gene encoding the adhesion molecule L1CAM. Finally, there are rare cases of adult-onset, X-linked HSP-like disorders that are allelic forms of adrenoleukodystrophy.

OTHER INHERITED MOTOR NEURON DISEASES

Other inherited motor neuron diseases are recognized. Some affect only the motor system; others are complex, multisystem degenerations. Fazio-Londe disease (progressive juvenile bulbar palsy) is a bulbar motor neuronopathy that begins before the third year. The arthrogryposes are a complex set of disorders with contractures at birth from motor neuron cell loss. These may be either sporadic or inherited as autosomal recessive, autosomal dominant, or X-linked traits. In the scapuloperoneal muscular atrophies there is neuropathic weakness in the shoulders muscles and the peroneal groups. This disease also shows considerable diversity with dominantly inherited midlife onset and early onset and possible X-linked forms.

ALS RISK FACTORS: A BRIDGE BETWEEN INHERITED AND SPORADIC ALS

Although most cases of ALS are not familial, it remains plausible that many individuals with sporadic ALS may have heightened susceptibility to factors such as environmental insults and the consequences of aging that challenge and ultimately disrupt motor neuron function and viability. Many such putative ALS risk factors have been considered. The status of polymorphisms in ApoE has been investigated because the ApoE4 allele confers a distinct risk for early onset in Alzheimer's disease. Studies do not clearly implicate ApoE as an ALS risk factor. However, in one large series, the rate of progression in sporadic ALS was more rapid in a cohort with higher levels of total serum apolipoprotein E. Ciliary neurotrophic factor (CNTF) is a potent trophic substance for motor neurons in vitro; inactivation of the CNTF gene in mice

causes motor neuron degeneration. It is therefore striking that some individuals lack CNTF. An initial report indicated that CNTF null heterozygotes are not over-represented in ALS patients. It has been suggested that individuals who are CNTF null homozygotes have an earlier onset but no change in survival. Because of its critical role in SMA, SMN has been evaluated as a risk factor in sporadic ALS. A large French study has concluded that heterozygosity for the major SMN locus, SMN1, is a risk factor for ALS; the same team has also reported that deletions at the minor SMN locus, SMN2, also confer heightened risk for ALS although a Spanish study failed to confirm this. Investigators in Holland did find an overrepresentation of homozygous deletion of the SMN2 gene and reported that this correlates with an increased rate of progression.

Mutations in the gene encoding the NF-H are present infrequently in some individuals with sporadic ALS, although this finding has been uniformly reproduced. Moreover, these mutations do not clearly comigrate with the disease trait in large ALS pedigrees showing a dominant inheritance pattern, suggesting that the mutations may define risk factors for the disease. Similarly, a single patient has been detected with sporadic ALS and a mutation in a glycosylation site of EAAT2; it is clear that this mutation results in reduced surface expression and reduced glutamate transport by EAAT2. As well, several patients have been identified with variants in the targeting sequence of the mitochondrial form of SOD, SOD2.

It is of great interest that a fraction of mice genetically modified to lack a hypoxia-sensing element in the promotor for the gene encoding vascular endothelial factor (VEGF) develop a slowly progressive motor neuron disease. The mechanism for this phenotype is not clear; it may be a consequence of depressed levels of VEGF, mediated either directly by insufficiency of a VEGF-mediated neurotrophic influence on neurons or indirectly via a vascular effect. This finding has prompted an analysis of variants in VEGF as risk factors for ALS. In a large study of large ALS cohorts in Sweden, Belgium and northern England, individuals homozygous for a haplotype associated with reduced levels of circulating VEGF had nearly a twofold increase in the risk of ALS; this effect was not evident in a fourth cohort from London.

The foregoing possible risk factors were selected because of their importance as determinants of motor neuron viability. Presumably, it will also be informative to study variants in genes that are important in coping with environmental toxins. Although this field, environmental genetics or genotoxicology, is nascent, the concept has applied to ALS; the observation that blood and bone levels of lead are increased in a cohort of ALS patients is being elucidated through the analysis of polymorphisms in serum proteins that bind lead.

116 Trinucleotide Repeat Disorders

HUDA Y. ZOGHBI

SUMMARY

Expansion of trinucleotide repeat sequences is the mutational mechanism in at least 16 neurological disorders, including fragile X type A syndrome, myotonic dystrophy, spinobulbar muscular atrophy, Huntington disease, and several others. The discovery of trinucleotide repeat expansions provides a biological explanation for "anticipation," the increase in disease severity and decrease in age of onset from one generation to the next, observed in all of these disorders. This chapter provides an overview of trinucleotide repeat disorders and discusses some of the findings in pathogenesis studies.

Key Words: dentatorubropallidoluysian atrophy; fragile X type A syndrome; Friedreich ataxia; Huntington disease; Machado-Joseph disease; myotonic dystrophy; spinobulbar muscular atrophy; trinucleotide repeat sequences.

INTRODUCTION

Expansion of trinucleotide repeat sequences is the mutational mechanism in at least 16 neurological disorders, including fragile X type A syndrome (FRAXA), myotonic dystrophy (DM), spinobulbar muscular atrophy (SBMA), Huntington disease (HD), and HD-like 2, several spinocerebellar ataxias (SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA12, and SCA17), dentatorubropallidoluysian atrophy (DRPLA), and Friedreich ataxia (FRDA). The discovery of trinucleotide repeat expansions provides a biological explanation for "anticipation," the increase in disease severity, and decrease in age of onset from one generation to the next, observed in all of these disorders. Although several polymorphic trinucleotide repeat sequences are abundant in the human genome, only a subset has been associated with disease states. These include trinucleotide repeats with CGG, CAG, CTG, or GAA. Although the majority of dynamic mutations are from expansion of unstable trinucleotide repeats, some involve other sequences such as tetranucleotide repeats (CCTG) in DM type 2, pentanucleotides (ATTCT) in SCA10, or a dodecamer repeat (C_4GC_4GCG) in progressive myoclonus epilepsy 1.

The mechanism underlying the expansion, and occasionally the contraction, of these repeats is being investigated. It is intriguing that the number of repeat units within the murine homologs of the genes involved in the above human disorders is relatively small, ranging from two to four repeats, and the repeats are frequently not polymorphic. This raises the question of whether dynamic mutations involving trinucleotide repeat instability are unique to humans and whether the mechanism involving pathological expansions is influenced by the length and variability within a particular repeat.

Several models have been suggested to explain the dynamic nature of expanded trinucleotide repeats: slipped strand structure during DNA replication, misalignment and excision repair, and unequal crossing-over. Available data support a model in which long repeats form unusual DNA structures, which then block or stall replication increasing the likelihood of expansions. Hairpin or slipped strand structures might result in error-prone processing by the DNA repair or replication machinery. Several of the normal trinucleotide repeat loci (FRAXA, SCA1, SCA2, and FRDA) are associated with repeat interruptions. In SCA1, a CAG repeat tract as large as 42 repeats but with one to three CAT interruptions is stable whereas an SCA1 allele with 40 "pure" CAG repeats is unstable. The stabilizing effect of repeat interruptions may be because of their ability to disrupt formation of unusual secondary DNA structures.

The disorders caused by trinucleotide repeat expansion can be divided into two major groups based on the position of the repeat within a specific gene locus and its subsequent effect on gene function. The first group, known as the noncoding repeat disorders, includes FRAXA, fragile X type E mental retardation (FRAXE), DM, SCA8, and 12, and FRDA. The second group, caused by expansion of a translated CAG repeat that encodes a glutamine tract, is referred to as "polyglutamine disorders" and includes SBMA, HD, SCA1, 2, 3, 6, 7, and 17, and DRPLA. Tables 116-1 and 2 summarize the salient clinical and genetic features of the disorders caused by trinucleotide repeat expansions. This chapter provides an overview of trinucleotide repeat disorders and discusses some of the findings in pathogenesis studies.

THE NONCODING REPEAT DISORDERS

FRAGILE X SYNDROME AND FRAGILE XE MENTAL RETARDATION FRAXA is probably the most common form of inherited mental retardation with an estimated prevalence of 1/4000 males. The main clinical feature in preadolescent males is mental retardation; in postpubescent males additional features include increased head size, enlarged ears, macroorchidism, narrow and elongated faces, and mild skeletal defects. MRI studies show decreased size of the posterior cerebellar vermis and hippocampus. Neuropathological studies reveal abnormal dendritic spines that are immature and appear long and tortuous. FRAXA, which

Table 116-1
Diseases Caused by Noncoding Triplet Repeat Expansions

Disorder	*Most common clinical features*	*Inheritance*	*Gene*	*Chromosome*	*Repeat*	*Normal repeat no.*	*Mutation range*	*Location*
Fragile X syndrome	Mental retardation, macro orchidism, macrocephaly, and mild skeletal abnormalities	XL	FMR1	Xq27.3	CGG	6–52	Premutation: 60–200[a] Full mutation: 230–1000+	5′ UTR
Fragile XE	Mental retardation	XL	FMR2	Xq28	GCC	7–35	Premutation: 130–150 Full mutation: 230–750+	5′ UTR
Friedreich ataxia	Ataxia, loss of proprioception, *pes cavis*, cardiomyopathy, diabetes	AR	FRDA1	9q13-21.1	GAA	6–34	Premutation: 80 Full mutation: 112–1700+	intron 1
Myotonic dystrophy	Myotonia and muscle weakness, cataracts, cardiac involvement, diabetes, and baldness	AD	DMPK	19q13	CTG	5–37	50–3000+	3′ UTR
Spinocerebellar ataxia type 8 (SCA8)	Ataxia and dysarthria	AD	SCA8	13q21	CTA/CTG	15–37	Usually 80–250	3′ UTR
SCA12	Ataxia and tremor	AD	PPP2R2B	5q31-q33	CAG	7–28	66–78	5′ UTR

[a]Male patients with premutation FMR1 alleles may develop ataxia, intention tremors and Parkinsonism.

Table 116-2
Diseases Caused by Coding CAG Repeat Expansions

Disorder	*Most common clinical features*	*Inheritance*	*Gene*	*Chromosome*	*Normal repeat no.*	*Mutation range*
Spinobulbar muscular atrophy	Proximal muscle weakness, bulbar dysfunction, gynecomastia	XL	AR	Xq13-21	11–33	38–66
Huntington disease	Cognitive impairment, depression, irritability, and chorea	AD	HD	4p16.3	6–39	36–121
Huntington disease-like 2	Cognitive impairment, depression, irritability, and chorea	AD	JPH3	16q24.3	6–27	35–57
Spinocerebellar ataxia type 1 (SCA1)	Ataxia, dysarthmia, brainstem dysfunction	AD	SCA1	6p23	6–44[a]	36–82
SCA2	Ataxia, hyporeflexia, slow, saccades	AD	SCA2	12q24.1	14–31	33–200
SCA3/Machado-Joseph disease	Ataxia, bulging eyes, dystonia, spasticity	AD	SCA3	14q32.1	12–41	55–84
SCA6	Late onset ataxia/sometimes “sporadic”	AD	CACNA1A	19p13	7–18	20–33
SCA7	Ataxia and visual loss because of retinal degeneration	AD	SCA7	3p12-13	4–35	37–460
SCA17	Ataxia, tremors	AD	TBP	6q27	29–42	47–55
Dentatorubropallidoluysian atrophy	Progressive ataxia, myoclonus, epilepsy, chorea, and dementia	AD	DRPLA	12p13.31	6–35	49–88

[a]Alleles with 21 or more repeats are interrupted by 1–3 (CAT) units; disease alleles contain pure CAG tracts.

was initially mapped to Xq27.3 based on the finding of a fragile site at this location, is an X-linked disorder with unusual penetrance. Approximately 30% of female carriers have borderline IQ, and 20% of males with genetic risk for FRAXA are normal. These observations led to the “Sherman paradox,” which described increasing penetrance in successive generations. The FRAXA gene known as *FMR1* was isolated using a positional cloning approach, and the mutation was one of the first dynamic mutations to be identified, an expansion of a CGG repeat within the 5′ untranslated portion of the gene. Normal alleles typically contain 7–54 repeats (30 being most common) often punctuated by AGG interruptions. Symptomatic males have 200 or more repeat units, whereas nonpenetrant males and carrier females have 70–150 repeats, which are referred to as premutational. Females with mental retardation typically have repeats with 200 or more units, but, in general, only 30% of females with repeats

over 200 have mental retardation, presumably resulting from the effects of X-inactivation patterns. The identification of the mutational basis of FRAXA clarified the Sherman paradox, and like other trinucleotide repeat mutations, provided a molecular basis for anticipation.

The *FMRI* CGG repeat is highly unstable in premutation alleles transmitted through a female meiosis. Females with 80 or more repeats have a virtual 100% mutation rate to a disease-causing expansion. The expansion of the CGG repeat leads to its hypermethylation and to methylation of a CpG island within the *FMR1* promoter, which in turn leads to loss of its transcription. Identification of other mutations in *FMR1* (deletions and point mutations) produced a phenotype similar to that in patients with fragile site and confirmed *FMR1* to be the only gene involved in pathogenesis of fragile XA. A mouse model lacking *Fmr1* exhibits macroorchidism and subtle learning and memory phenotypes.

A progressive neurological disorder has been documented in males who have a premutation allele in the 55–230 repeat range. These males typically develop tremors, ataxia, and Parkinsonian features in the sixth decade of life. Imaging studies reveal global brain atrophy and loss of subcortical white matter. Neuropathological studies in postmortem tissues from patients and from a mouse model carrying a premutation allele revealed abnormal protein accumulations within neurons reminiscent of findings in polyglutamine neurodegenerative disorders.

FMR1 is a widely expressed, highly conserved gene with highest levels in brain and testes. The functions of the *FMR1* gene product (FMRP) are beginning to be elucidated. FMRP, an RNA-binding protein, associates with actively translating polyribosomes and regulates the translating machinery in dendritic spines thus regulating RNA translation at the synapse. Some of the FMRP's mRNA ligands have been identified based on a signature binding element (G quartet) in many of these targets. This work identifies molecules that are likely to be key in causing the mental retardation phenotype in this syndrome.

Fragile XE syndrome is milder than FRAXA and does not cause other physical features. Patients have mild mental retardation, learning deficits, attention deficits, and hyperactivity. The prevalence of FRAXE is 1–4% of FRAXA. FRAXE is caused by a CGG expansion in the *FMR2* gene. *FMR2* is widely expressed with the highest levels being in the hippocampus and amygdala. FRAXE is caused by the loss of function of *FMR2* because of its transcriptional silencing. The precise function of *FMR2* is not well delineated but it is suspected to play a role in transcriptional regulation based on protein homology data.

MYOTONIC DYSTROPHY DM, the most common muscular dystrophy affecting adults, is an autosomal-dominant disorder with a wide range of severity from a frequently lethal form in newborns (congenital DM1) to almost asymptomatic expression in adults. Clinical features include muscle weakness, myotonia, cataracts, cardiac arrhythmias, endocrine dysfunction, male-pattern baldness, and male infertility. The disease typically increases in severity and occurs earlier with successive generations—anticipation. Congenital DM1, the most severe form of the disease, is characterized by severe hypotonia, respiratory insufficiency, and feeding difficulties. Congenital DM1 is usually transmitted from mothers, who often have mild to undetectable symptoms.

DM is caused by expansion of a CTG repeat located in the 3′ untranslated region of a gene that encodes a protein kinase. The number of repeats varies from 5 to 20 in the normal population whereas in DM1 families it ranges from 50 to 4000.

The DM1 gene product, myotonin protein kinase (DMPK), was confirmed to be a serine/threonine kinase using in vitro assays of the recombinant protein. Mice lacking the *Dmpk* gene develop a late-onset progressive myopathy, but lack other features of DM, including myotonia and male infertility.

The molecular pathogenesis of DM1 is complex and at least three different mechanisms have been suggested to explain how CTG expansion causes the complex phenotype. DMPK haploinsufficiency is proposed to occur because of massive expansion of the CTG repeat, which might hinder the cytoplasmic translocation and translation of the mutant mRNA. The second mechanism invokes interference with transcription of genes in the vicinity of the CTG repeat. Suppression of the expression of *SIX5* gene is proposed to underlie the cataract phenotype in DM1 given that mice lacking *Six5* develop cataracts. The third mechanism proposes that DMPK RNA with an expanded CUG tract binds to and sequesters other proteins thus interfering with their function. Several pieces of evidence support such a mechanism. Transgenic mice expressing mRNA with a CUG tract (the thymine is replaced by uracil in RNA) of 250 repeats (outside the context of DMPK) develop myotonia and myopathy. In patient tissue and in tissues from animal models harboring expanded alleles, the mutant RNA accumulates in nuclear foci that are thought to sequester and alter the function of CUG-binding protein. There is evidence that CUG-binding protein is critical for the normal splicing of cardiac troponin T and the insulin receptor, and that the splicing patterns of these two genes are altered in DM1 tissues. Disruption of the functions of cardiac troponin T and the insulin receptor could contribute to the cardiac abnormalities and diabetes in DM1. A second DM locus (DM2) has been identified and found to result from expansion of a CCTG repeat in the first intron of the zinc finger protein 9 (ZNF9) gene on chromosome 3q21. Normal alleles typically have less than 26 repeats, whereas the expanded alleles have 75–11,000. DM2, an autosomal-dominant disorder, is clinically similar to DM1. The accumulation of mutant ZNF9 RNA in nuclear foci in DM2 suggests that it also shares a similar pathogenic mechanism with DM1, whereby mutant RNAs sequester RNA-binding proteins that may regulate splicing of genes involved in insulin homeostasis and normal muscle function.

FRIEDREICH ATAXIA FRDA is the most common inherited ataxia affecting 1 in 30,000 individuals. It is an autosomal-recessive disorder characterized by progressive gait ataxia that usually manifests between 5 and 10 yr of age, but earlier and later-onset forms have been reported. Loss of proprioception, dysarthria, tremors, and abnormal pursuit and saccades develop early in the disease course. Additional neurological features may include cataracts, retinitis pigmentosa, and optic atrophy. The disease progresses relentlessly forcing patients to be wheel chair bound in the second or third decade. Cardiomyopathy occurs in more than two-thirds of patients and is often symptomatic. Concentric left-ventricular hypertrophy (LVH) occurs in 40% of the patients and significantly increases the risk of death. ECG abnormalities are common (approx 80% of patients) and sometimes precede the ataxia. Diabetes occurs in 10% of the patients and an additional 20% have abnormal glucose tolerance. Pathological changes in FRDA include degeneration of the posterior columns, dorsal root ganglia neurons, and corticospinal tracts. Cerebellar and pontine degeneration occur in the late stages of the diseases.

FRDA is most commonly caused by expansion of an unstable GAA repeat in the first intron of the *FRDA* (*X25*) gene. Normal alleles have 7–34 repeats whereas disease alleles are typically more than 100 repeats. Rare patients are compound heterozygotes for a repeat expansion and sequence alteration. The gene product frataxin is a widely expressed mitochondrial protein and is usually drastically reduced in FRDA because the expansion interferes with its transcription. A strong correlation exists between GAA repeat size and disease severity: the longer the repeat the lower the levels of frataxin and the more severe the disease. Studies of a yeast frataxin homolog (Yfh1) focused attention on the role of frataxin in iron homeostasis. That mice lacking frataxin develop a deficiency in respiratory chain complex activities and have intramitochondrial iron accumulation further refined the site and mechanism of pathogenesis within the cell. The iron accumulation in mitochondria of animal models and human FRDA hearts was associated with increased sensitivity to oxidative stress. These findings inspired therapeutic strategies aimed at boosting antioxidant activity in the cell by providing antioxidants such as coenzyme Q10 (CoQ10) and its short-chain analog idebenone. Treatment of FRDA patients with CoQ10 and vitamin E for 6 mo improved muscle mitochondrial ATP production, but a functional significance of this change was not demonstrated. Three studies used idebenone at 5 mg/kg/d for several months to 1 yr. Two of these were open label and one was a placebo-controlled, double blind study. All three studies demonstrated significant reduction in interventricular septum thickness and/or left-ventricular mass index. The clinical significance of the reduction in LVH was not demonstrated and there was no evidence of an effect on the ataxia. Although a change in the clinical and neurological course was not demonstrated, the preliminary findings of reduced LVH after idebenone therapy are encouraging and call for additional clinical studies designed to assess cardiac and neurological outcome measures in FRDA.

SPINOCEREBELLAR ATAXIA TYPE 8 AND TYPE 12 Two SCAs are caused by expansion of trinucleotide repeats that are outside the coding region of the respective gene. SCA8 is caused by expansion of an untranslated CTG repeat in the 3′ end of a processed noncoding mRNA. The 5′ end of the SCA8 gene overlaps, in the opposite direction, the 5′ end of Kelch-like 1 that encodes an actin-binding protein. Normal alleles have 20–50 repeats and disease-causing alleles contain 100–250 repeats. Intriguingly, very large alleles (250–800 repeats) do not cause a phenotype. Exactly why large expansions are not deleterious is not known, but one hypothesis is that such expansion may interfere with RNA processing or stability thus a toxic expanded RNA will not be generated or is rapidly degraded. SCA12 is a rare SCA caused by expansion of an untranslated CAG repeat in the 5′ untranslated region of the brain-specific regulatory subunit of the protein phosphatase PP2A (PPP2R2B). The normal range of CAG repeat is 7–28 whereas expanded alleles have 66–78 repeats. The pathogenic mechanism in SCA12 is not yet understood and it is not known if the repeat expansion affects the function of PPP2R2B or that of another gene.

DISEASES CAUSED BY CODING TRINUCLEOTIDE REPEATS: THE POLYGLUTAMINE DISORDERS

The polyglutamine neurodegenerative disorders include SBMA, HD, DRPLA, and various SCAs. All these diseases result from an expansion of an unstable CAG repeat that encodes a glutamine tract in the respective protein. This group of diseases shares many clinical and pathophysiological features in spite of the diverse group of genes involved. First, all these diseases are inherited in an autosomal-dominant manner except SBMA, which is X-linked but dominant at the cellular level. Second, all these disorders are late onset with most patients developing symptoms in the third or fourth decade. There is an inverse correlation between repeat size and age of onset for each of these disorders. The intergenerational repeat instability, particularly expansions of paternally transmitted repeats, leads to anticipation in successive generations and to the juvenile onset of disease. Third, a gain of function mechanism is responsible for the neurodegenerative phenotype given that loss of function or haploinsufficiency of several of these genes leads to a phenotype that is distinct from that caused by CAG repeat expansion. Last, all these disorders appear to share at least one common pathogenic mechanism at the cellular level: the expanded polyglutamine tract is thought to alter the conformation, folding, and/or degradation pattern of the native protein thus leading to its accumulation. These accumulated proteins have various toxic effects depending on their normal function, interacting partners, and subcellular localization patterns.

It is curious that in each of these disorders there is a group of particularly vulnerable neurons in spite of the overlapping and wide expression patterns of the various gene products. As the CAG repeat size expands beyond 80–100 repeats to cause childhood or infantile disease the selective neuronal vulnerability disappears and the overlap in clinical and neuropathological findings becomes apparent. These findings highlight a commonality to some of the pathogenic mechanisms and raise the possibility that most neurons become equally vulnerable if sufficient levels of the misfolded mutant proteins accumulate in them. The following section provides an overview of each disorder, followed by a discussion of pathogenic mechanisms and translational research efforts.

SPINOBULBAR MUSCULAR ATROPHY (KENNEDY DISEASE) SBMA is an X-linked disorder characterized by proximal muscle weakness, bulbar dysfunction, and partial loss of secondary sexual characteristics. The clinical findings of lower motor neuron disease, gynecomastia, and impotence led to the hypothesis that SBMA may result from dysfunction of the androgen receptor (AR) given that this receptor is expressed in spinal and cranial motor neurons. The SBMA locus has been mapped to the long arm of the X chromosome and subsequently determined the mutation in SBMA to be an expansion of the CAG repeat within the first exon of the *AR* gene. Normal alleles contain 9–36 repeats, and expanded alleles contain 38–66 repeats.

The AR is a member of the steroid hormone receptor family and typically on binding of their ligand (androgen in the case of AR) in the cytoplasm, the complex is translocated to the nucleus in which it regulates transcription of hormone responsive genes. The expansion may cause partial loss of receptor function given some signs of androgen insensitivity in males but the predominant effect is a toxic gain of function because total lack of AR causes testicular feminization and not motor neuron degeneration. Several transgenic mouse models using portions or full-length AR with variable lengths of the CAG tract have been generated. One study demonstrated that when full-length AR with 97 CAG repeats is expressed at sufficiently high levels in mice, the SBMA phenotype is reproduced in a sex-limited pattern. Male mice developed motor neuron disease that resolved on castration; female mice were spared unless they were treated with testosterone. This study demonstrated the importance of androgen and the translocation of the hormone/receptor complex to the nucleus for pathogenesis.

Based on these findings interventional trials that reduce the male hormones are being investigated to see if they will curb the toxicity of the mutant AR in SBMA patients.

HUNTINGTON DISEASE HD is characterized by chorea, memory deficits, affective disturbance, and changes in personality. Dystonia, rigidity, and other involuntary motor impairments may occur. Patients with juvenile-onset suffer from rigidity, epilepsy, severe dementia, and rapid disease progression. Neuropathologically, HD is characterized by severe atrophy of the neostriatum (worse in the caudate), volume loss in the globus pallidus, and some cortical atrophy. The medium-sized spiny striatal neurons appear to be the most vulnerable neurons in HD. Purkinje cells are vulnerable in juvenile-onset cases. HD is caused by expansion of a CAG repeat in the first exon of the *HD* gene. Normal alleles have 6–34 repeats whereas disease causing alleles range from 36 to 121. The *HD* gene encodes for huntingtin, a protein that is essential for normal neuronal development and viability of the organism as demonstrated from studies of various knock-out mouse models. Gain of function animal models that express full length or truncated portions of HD with varying length repeats reproduce features of HD. Abnormal nuclear and neuropil aggregation of huntingtin has been documented in both postmortem human tissues and tissues from various mouse models. A HD-like 2 disorder has been reported in patients that have features of HD but no evidence of CAG repeat expansion at the HD locus. HD-like 2 is caused by expansion of a trinucleotide repeat in an alternatively spliced exon of the gene encoding junctophilin-3. The repeat is predicted to be either translated or in a 3′ untranslated region depending on which splice acceptor site is used during RNA processing. Thus the mechanism mediating the pathogenesis of HD-like 2 is not yet understood.

Various clinical trials in transgenic mouse models and human patients include treatment protocols using CoQ10, creatine, minocycline, remacemide, and riluzole. Although several of these therapies showed benefit in the mouse models, the data in humans have not demonstrated significant effects for CoQ10 or remacemide. Studies with riluzole, creatine, and minocycline continue.

DENTATORUBROPALLIDOLUYSIAN ATROPHY DRPLA is a rare autosomal-dominant neurodegenerative disorder, characterized by progressive ataxia, myoclonus, epilepsy, chorea, athetosis, and dementia. The mutation causing DRPLA was identified using the candidate gene approach and determined to involve an expansion of a CAG repeat within a novel gene that maps to human chromosome 12p. DRPLA patients have an expanded allele in the 49–88 repeat range in addition to the normal allele, which typically contains 6–35 repeats. The size of the expanded allele typically increases when paternally transmitted, with larger alleles causing juvenile-onset cases. The DRPLA mutation was found in an African American family with Haw River syndrome (HRS). HRS differs from DRPLA in the absence of myoclonic epilepsy and presence of demyelination of the subcortical white matter.

The DRPLA gene product, atrophin-1, is a widely expressed protein that localizes to both the cytoplasm and nucleus. Studies of its *Drosophila* homolog suggest that atrophin-1 may function as a transcriptional repressor. Patients with DRPLA suffer from neuronal loss in the dentate nucleus, globus pallidus, thalamus, and subthalamic nucleic. Severe demyelination and axonal degeneration is documented in the superior cerebellar peduncle and subcortical white matter. Basal ganglia calcifications are also noted.

Transgenic mice expressing full-length atrophin-1 develop ataxia, tremors, seizures, and premature death. Abnormal accumulation of atrophin-1 is noted in the nuclei of several neuronal populations similar to what is observed in postmortem human tissue.

SPINOCEREBELLAR ATAXIA TYPE 1 The main clinical features in SCA type 1 (SCA1) include gait ataxia, dysarthria, and dysmetria. As the disease progresses, brainstem involvement results in facial weakness, tongue atrophy, severe dysarthria, and dysphagia. Hyperreflexia may be detected early in the course of the disease, but in later stages the patients develop muscular atrophy, hypotonia, and hyporeflexia. Other, less consistent findings observed in some patients include optic nerve atrophy, ophthalmoparesis, and loss of proprioception and vibration sense. The disease typically manifests in the third to fourth decade, progresses over 10–15 yr, and results in death from brainstem dysfunction. Earlier age of onset and increase in the severity of the phenotype is observed in later generations of SCA1 kindreds.

Imaging studies in SCA1 patients reveal atrophy of the brachia pontis and anterior lobe of the cerebellum and enlargement of the fourth ventricle. Typical neuropathological findings in SCA1 include cerebellar atrophy with loss of Purkinje's cells and dentate nucleus neurons, presence of "torpedoes," which are swollen axons of degenerating Purkinje's cells, and severe neuronal degeneration in the inferior olive and to a lesser degree in cranial nerve nuclei III, IV, IX, X, and XII. Demyelination in the restiform body, brachium conjunctivum, spinocerebellar tracts, and posterior columns is frequently noted.

SCA1 results from expansion of a highly polymorphic CAG repeat that encodes a polyglutamine tract in the protein ataxin-1. Normal alleles contain 6–44 repeats that typically have 1–4 CAT interruptions when beyond 20 repeats. Disease alleles have a pure tract of uninterrupted CAG trinucleotides ranging from 39 to 82 repeats. Ataxin-1 is a protein of unknown cellular function. Loss of function in mice causes impaired motor learning but no ataxia. Transgenic and knock-in mouse models reproduce clinical and pathological features of SCA1. Mutant ataxin-1 localizes to a single ubiquitin-positive nuclear inclusion in neurons of SCA1 patients and mice. Studies of SCA1 transgenic mice and flies provided insight about the importance of protein folding and degradation in SCA1 pathogenesis as discussed later.

SPINOCEREBELLAR ATAXIA TYPE 2 SCA type 2 (SCA2) is characterized by ataxia, dysarthria, tremor, nystagmus, and slow saccades. Hyporeflexia occurs in later stages of the disease and some patients suffer cognitive impairment. Infantile SCA2 has been documented and is characterized by neonatal hypotonia, developmental delay, bulbar dysfunction, and retinitis pigmentosa. Neuropathologically SCA2 is characterized by loss of cerebellar Purkinje cells and brainstem neurons. Atrophy of fronto-temporal lobes and loss of nigral neurons have also been reported. The SCA2 CAG repeat is not very polymorphic with the majority of alleles containing 22 or 23 repeats; normal range is 14–31 repeats interrupted by two CAA triplets. Disease alleles contain a pure CAG tract that ranges from 33 to 200 repeats. A patient with 33 repeats has onset at 86 yr of age whereas the one with 200 repeats has neonatal onset. The SCA2 gene product, ataxin-2, is a novel protein of unknown function. Genetic studies in *Drosophila* provided insight about the function of the fruit fly homolog of ataxin-2 (Datx2). Flies lacking Datx2 manifest sterility, abnormal bristle morphology, cellular degeneration and lethality. These phenotypes appear to result from defects in actin filament formation raising the possibility that Datx2 is a regulator of actin filament formation. Like other mutant polyglutamine proteins, ataxin-2 accumulates in SCA2 brains and in Purkinje cells of mice that overexpress

a mutant allele. Interestingly, mutant ataxin-2 predominantly accumulates in the cytoplasm in contrast to most other polyglutamine disorders in which the mutant proteins accumulate in the nucleus. This is most likely because of ataxin-2's normal cytoplasmic subcellular localization.

MACHADO-JOSEPH DISEASE/SPINOCEREBELLAR ATAXIA TYPE 3 Machado-Joseph disease (MJD) is characterized by progressive ataxia, external ophthalmoplegia, bulging eyes, facial and lingual fasciculations, muscle atrophy, dystonia, and spasticity. Dementia and extrapyramidal findings occur in approx 20% of patients. Neuropathological findings include severe neuronal loss in the striatum and substantia nigra, with moderate abnormalities in the dentate nucleus and red nucleus. The mutational mechanism in MJD involves the expansion of a CAG repeat that lies within a novel gene on chromosome 14q32.1. Normal alleles contain 12–40 repeats, whereas expanded alleles contain 55–84 repeats. SCA3, clinically distinct from MJD and resembling SCA1, is also caused by CAG expansions within the *MJD* gene.

Ataxin-3 is a predominantly cytoplasmic protein, although when mutated it accumulates in nuclei of neurons. Transgenic mice and flies harboring truncated ataxin-3 with expanded polyglutamine tracts revealed the toxicity of such expanded tracts and highlighted the importance of protein misfolding in the pathogenesis of polyglutamine-induced degeneration.

SPINOCEREBELLAR ATAXIA TYPE 6 Patients with SCA type 6 (SCA6) present with mild, slowly progressive ataxia and dysarthria; as the disease worsens, patients suffer from pronounced incoordination, tremor, and dysphagia. Some patients exhibit horizontal gaze-evoked and vertical nystagmus and some develop mild neuropathy.

Neuropathological findings in SCA6 include marked cerebellar atrophy with severe loss of cerebellar Purkinje cells and moderate loss of cerebellar granule cells, dentate nucleus neurons, and neurons of the inferior olive.

SCA6 is caused by a CAG repeat expansion in the α_{1A}-voltage dependent calcium channel (*CACNA1A*). Voltage-sensitive calcium channels are multimeric complexes made of the pore-forming α_{1A}-subunit and several regulatory subunits. These channels mediate calcium entry into neurons and are abundant in cerebellar Purkinje cells and granule neurons. Consistent with this, the mutant α_{1A}calcium channels aggregate in the cytoplasm of SCA6 Purkinje cells. These accumulations occur in the peripheral perikaryal cytoplasm and in the proximal dendrites but not in the nucleus.

The CAG repeat in *CACNA1A* is exceptionally small, with fewer than 18 repeats on normal alleles. Disease-causing alleles are also small and contain 20–33 CAG repeats. These small expansions, however, are sufficient to increase α-1A protein expression at the cellular surface and thus Ca^{2+} current. Missense, splice, and protein-truncating mutations in *CACNA1A* have been reported in episodic ataxia type 2 (EA2) and familial hemiplegic migraine. Furthermore, the tottering and tottering-leaner mice bear nonexpansion mutations in the mouse homolog. That some patients with SCA6 experience episodic ataxia in the early stages of their disease raises the possibility that SCA6 and EA2 may represent different points along a phenotypic continuum of the same disease.

SPINOCEREBELLAR ATAXIA TYPE 7 Of the patients with SCA type 7 (SCA7), approximately half present with cerebellar ataxia and visual deficits; the majority of the remaining half present with cerebellar ataxia but may develop visual dysfunction after decades of disease. SCA7 patients lose visual acuity because of a progressive pigmentary macular degeneration. Patients initially lose central vision but have intact peripheral and night vision. Secondary optic atrophy and bilateral blindness occur in the disease's later stages. Additional features of SCA7 include increased reflexes and spasticity, slow saccades, ophthalmoplegia, and hearing deficits. Behavioral disturbances such as auditory hallucinations, progressive psychosis, depression, and delusions have been reported. Infantile SCA7 is severe and characterized by severe hypotonia, patent ductus arteriosus, congestive heart failure, and the visual and neuronal deficits. These infants typically die in the first year of life.

Neuronal loss occurs primarily in the cerebellum, inferior olive, and some cranial nerve nuclei. Degeneration of cones and rods as well as hypomyelination of the optic tract and gliosis of the lateral geniculate body and visual cortex are also characteristics of SCA7. Electron microscopy studies of skeletal muscles of SCA7 patients reveal mitochondrial abnormalities, such as subsarcolemmal accumulations of rounded mitochondria and frequent autophagic vacuoles.

The polyglutamine tract is near the amino terminus of the *SCA7* gene product, ataxin-7. Normal alleles contain pure CAG tracts ranging from 4 to 35 repeats whereas expanded alleles contain 37–460 repeats. The SCA7 mutation is highly unstable and manifests the most extreme intergenerational CAG repeat instability, with an expansion of 263 repeats in one paternal transmission.

Ataxin-7 is of very low abundance in the cell, probably because of its rapid degradation. Ataxin-7, is a component of a protein complex that has a histone acetyl transferase activiy, and thus must play a role in transcriptional regulation. The *SCA7* RNA shows ubiquitous expression, with high levels in the heart, placenta, skeletal muscle, pancreas, and brain. Within the central nervous system, the *SCA7* transcript is most abundant in the cerebellum. In SCA7 patients, ataxin-7 nuclear aggregates were observed in the brainstem, especially pons and inferior olive and, in one juvenile-onset patient, in the cerebral cortex. Studies in several transgenic models of SCA7 and a knock-in model of the disease demonstrate that mutant ataxin-7 alters transcription of at least photoreceptor-specific genes, suggesting that transcriptional dysregulation is an important component of pathogenesis.

SPINOCEREBELLAR ATAXIA TYPE 17 SCA type 17 (SCA17) manifests with ataxia, dementia or features of Parkinsonism, such as truncal dystonia, dysmetria, bradykinesia, accelerated gait, and retropulsion. Epilepsy is typically a late feature but rarely occurs early in the course.

Imaging studies of SCA17 patients reveal diffuse cortical and cerebellar atrophy. Neuropathological examination reveals loss of small neurons in the thalamus, frontal and temporal cortical regions, caudate nucleus, and putamen. The cerebellum shows moderate Purkinje cell loss and increased gliosis.

SCA17 is caused by a CAG repeat expansion in the gene encoding the TATA-binding protein (TBP), a general transcription initiation factor. Normal repeat tracts contain 29–42 CAGs whereas disease alleles range from 47 to 55 repeats. TBP is the DNA-binding subunit of RNA polymerase II transcription factor D, a multi-subunit complex critical for the transcription of most genes.

PATHOGENESIS OF POLYGLUTAMINE DISORDERS

The presence of abnormal protein aggregates in neurons is common in polyglutamine disorders. This feature is shared with other neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, frontotemporal dementia, amyotrophic lateral

sclerosis and prion encephalopathies. Studies in cell culture, animal models, and human tissues led to the discovery that the nuclear protein aggregates stain positively for ubiquitin, molecular chaperones, and components of the proteasome. These findings led to the hypothesis that the expanded polyglutamine tracts alter the conformation of the host protein causing it to misfold and resist degradation. Data from an SCA7 knock-in mouse model that carries an expanded CAG tract within the endogenous SCA7 locus revealed gradual accumulation of mutant ataxin-7. Because wild-type ataxin-7 is normally rapidly degraded, the gradual increase in the levels of the mutant protein is consistent with the hypothesis that the expanded protein resists degradation.

Other evidence in support of the importance of the ubiquitin-proteasome pathway in pathogenesis comes from cellular and genetic studies. Decreasing the amounts of ubiquitin and/or some of the enzymes typically involved in ligating ubiquitin to protein substrates (so that they can be targeted for proteasomal degradation) enhanced the neurodegenerative phenotypes in *Drosophila* and mouse SCA1 models. To boost the cells' ability to deal with mutant polyglutamine proteins, several investigators overexpressed chaperones in cells and in model organisms of the polyglutamine proteinopathies. Molecular chaperones are proteins that typically promote proper folding of newly synthesized or misfolded proteins or usher them to be degraded by the proteasome if they cannot be folded properly. Chaperone overexpression clearly suppressed the neurodegenerative phenotypes in flies expressing either an expanded polyglutamine tract, a portion of mutant ataxin-3, or full-length ataxin-1. Chaperone overexpression also improved the motor function in SCA1 mice. These data provide evidence in support of a common pathogenic mechanism in polyglutamine disorders and identify chaperones as a potential therapeutic target in this class of disorders. If the chaperone activity of neurons can be boosted pharmacologically, disease progression might be slowed.

Exactly how the expanded polyglutamine protein induces neuronal dysfunction and degeneration in each of the disorders is not understood but some implicated mechanisms are being investigated. Because many of the protein accumulations occur in the nucleus, several investigators focused on the role of transcription in pathogenesis. Transcriptional dysregulation has been confirmed in mouse models of SCA1, SCA7, and HD. Alterations in the nuclear distribution and activity of the transcriptional activator CREB-binding protein (CBP) in mouse and cellular models and in human tissues made it an excellent candidate for mediating some of the pathogenic effects. CBP is known to enhance transcription through enhancing histone acetylation and thus rendering chromatin more open and accessible to the transcriptional machinery. Alterations found in CBP activity in some polyglutamine disorders raised the question of whether decreasing histone deacetylation would have beneficial effects. This proved to be the case in *Drosophila* and in mouse models bearing exon 1 of huntingtin with an expanded repeat tract and in cells expressing mutant AR and HD proteins. The histone deacetylase inhibitors suberoylamide hydroxamic acid and sodium butyrate suppressed neuronal degeneration and improved the viability in these model systems. Thus histone deacetylase inhibitors constitute another potential therapeutic target for this class of diseases.

Studies of ataxin-1, its modifications and interactions revealed another potential pathway for intervention. Ataxin-1 is phosphorylated by Akt protein kinase, allowing ataxin-1 to interact with the protein 14-3-3, which in turn hinders its degradation. Genetic studies in mice and flies revealed that interfering with this phosphorylation by mutating the amino acid that is normally phosphorylated by Akt or by decreasing Akt levels suppresses neuronal degeneration in SCA1 mice and flies, respectively. These findings point to inhibitors of Akt (and its upstream activator phosphotidyl inositol 3-kinase) as potential therapeutic targets for evaluation in SCA1 mice.

SUMMARY AND CLINICAL IMPLICATIONS

The finding that expansion of trinucleotide repeats is the mutational mechanism in the described neurological disorders greatly facilitates the diagnosis of these diseases and provides options for genetic counseling. In the case of dominantly inherited ataxias, the identification of these mutations allows a rational classification of this highly heterogeneous group of diseases in addition to facilitating diagnosis. Molecular testing for trinucleotide repeat expansions should be considered as the leading diagnostic test in trying to evaluate patients with dominantly inherited ataxia, progressive degenerative disorders characterized by chorea, dementia with or without seizures, X-linked patterns of lower motor neuron disease, congenital muscle disorders and suspected DM, and mental retardation. Testing for the HD, DRPLA, and SCA mutations in asymptomatic individuals who are at risk should be restricted to adults who have undergone extensive psychological and genetic counseling, given the devastating nature of these diseases. In children these tests should be limited to those already symptomatic. In the case of FRAXA, the molecular analysis of the CGG repeat is superior to the cytogenetic approach traditionally used for identifying the fragile site, owing to its sensitivity and accuracy. However, chromosomal analysis in patients with mental retardation is still extremely valuable given the relative high likelihood of identifying other cytogenetic abnormalities. The finding that male patients with premutation alleles at FMR1 develop a late onset progressive ataxia and tremors should entice clinicians to obtain careful family history about mental retardation and ovarian failure in the descendents of these males. Importantly, a DNA test in these patients might prove beneficial for diagnosing this new emerging clinical entity and for counseling their descendents about risk of future expansions. The progress in pathogenesis studies has been hastened by the power of genetic models and cell and molecular biology techniques. These studies are revealing pathways that are potential therapeutic targets. Ongoing interventional trials in FRDA and potentially in several of these diseases are encouraging.

The availability of excellent mouse models for several polyglutamine disorders and the identification of several potential therapeutic targets will allow rigorous design of preclinical trials to evaluate safety and efficacy. In the case of SBMA, preclinical data suggest that manipulating androgen levels in affected males is a therapeutic strategy. The finding that neurons can recover if the production of the mutant protein is halted in conditional mouse models of HD and SCH provide hope that some treatments might reverse aspects of the disease in symptomatic individuals. The delayed onset of these diseases provides a window of opportunity to intervene before clinical symptoms become apparent. The challenge, however, is identifying outcome measures and biological markers that can be used to gage the effect of interventional trials because of the variable onset in this group of diseases and because their course typically spans decades.

117 Parkinson's Disease

Deepak M. Sampathu and Virginia M.-Y. Lee

SUMMARY

Parkinson's disease (PD), which is the most common neurodegenerative movement disorder, is clinically characterized by resting tremor, rigidity, bradykinesia, and postural instability. The pathological hallmarks of PD include loss of dopaminergic neurons in the substantia nigra pars compacta as well as the presence of abnormal protein deposits known as Lewy bodies in some of the surviving nigral neurons. The loss of dopaminergic neurons in the substantia nigra pars compacta results in striatal dopamine deficiency, which accounts for the motor impairments of patients with PD. Although the precise etiology remains unclear, several environmental and genetic factors have been implicated in the molecular pathogenesis of PD. This chapter will systematically discuss each of these factors and their putative pathogenic mechanisms.

Key Words: Basal ganglia; dopamine; L-DOPA; Lewy body; neurodegeneration; oxidative stress; parkin; Parkinson's disease; substantia nigra; α-synuclein.

INTRODUCTION

Descriptions of what may have been Parkinson's disease (PD) are found in traditional Indian medical *(Ayurvedic)* texts written long ago (approx 4500 BCE–1000 BCE). The Sanskrit term *kampavata* described a clinical syndrome consisting of tremor and akinesia, which remarkably was treated with a formulation made using beans from the plant *Mucuna pruriens*, now known to contain L-DOPA. Although such descriptions and others point to the existence of PD before the industrial revolution, the first formal description of the disorder came in 1817, when the English physician James Parkinson wrote a short pamphlet entitled "An Essay on the Shaking Palsy," in which he described resting tremor, flexed posture, festinating gait, and "lessened muscular power" in six patients, some of whom he had only casually observed on the streets of London. Beginning in 1861, a series of landmark publications by the French physician Jean-Martin Charcot expanded on Parkinson's description and clarified the cardinal features, emphasizing that "slowness in execution of movement" (or bradykinesia), rather than weakness, contributed to the disorder. Charcot suggested the term "Parkinson's disease" to replace the earlier designation of "shaking palsy," perhaps to reflect that marked weakness is not a feature and patients do not always have tremor.

In spite of Charcot's detailed clinical descriptions of PD, he never fully comprehended its neuroanatomic basis. In 1893, Blocq and Marinesco suggested that a lesion of the substantia nigra (SN) might be responsible, based on a case of hemiplegic parkinsonism in which a tuberculoma had destroyed the region. Subsequent pathological investigation confirmed this idea, as a 1919 study by Tretiakoff found degeneration of the SN a constant feature of PD. Tretiakoff also reported that surviving nigral neurons could contain eosinophilic intraneuronal inclusions (Lewy bodies [LBs]), which had been previously described in the dorsal motor nucleus of the vagus and substantia innominata of PD patients by Friedrich Lewy in 1912.

CLINICAL AND PATHOLOGICAL FEATURES

PD is the most common neurodegenerative movement disorder and a significant burden to society, afflicting at least 1% of individuals greater than 65 yr. The major triad of classic signs of PD is resting tremor, rigidity, and bradykinesia, but additional cardinal features include flexed posture, loss of postural reflexes, and the freezing phenomenon. The clinical diagnosis of parkinsonism requires at least two of these features, with at least one being bradykinesia or resting tremor. As the disease progresses, PD patients may suffer from behavioral and cognitive disturbances, including dementia, which is increasingly recognized in the elderly. Idiopathic PD can be best differentiated clinically from secondary causes of parkinsonism by the combination of the presence of resting tremor, asymmetry of signs and symptoms, and a good response to L-DOPA. Although clinical diagnosis of PD is fairly accurate (approx 75% in some reports), misdiagnosis, even by well-trained neurologists, is still a significant problem because of the existence of many secondary causes of parkinsonism, and neuropathological confirmation is required for definitive diagnosis.

The pathological hallmarks of PD include dopaminergic neuronal loss in the substantia nigra pars compacta (SNpc) and the presence of fibrillar proteinaceous inclusions known as LBs in the cytoplasm some of the surviving nigral neurons (Fig. 117-1A). LBs, which are easily detected by α-synuclein immunostaining and to a lesser extent by ubiquitin immunoreactivity, can also be found in other brainstem nuclei, cortical regions, and autonomic ganglia. In addition to LBs in affected areas, proteinaceous deposits termed Lewy neurites (LNs) are found in neuronal processes (Fig. 117-1B). The loss of dopaminergic neurons in the SNpc results in a profound deficiency in striatal dopamine, which underlies the classic motor signs and symptoms of PD, particularly

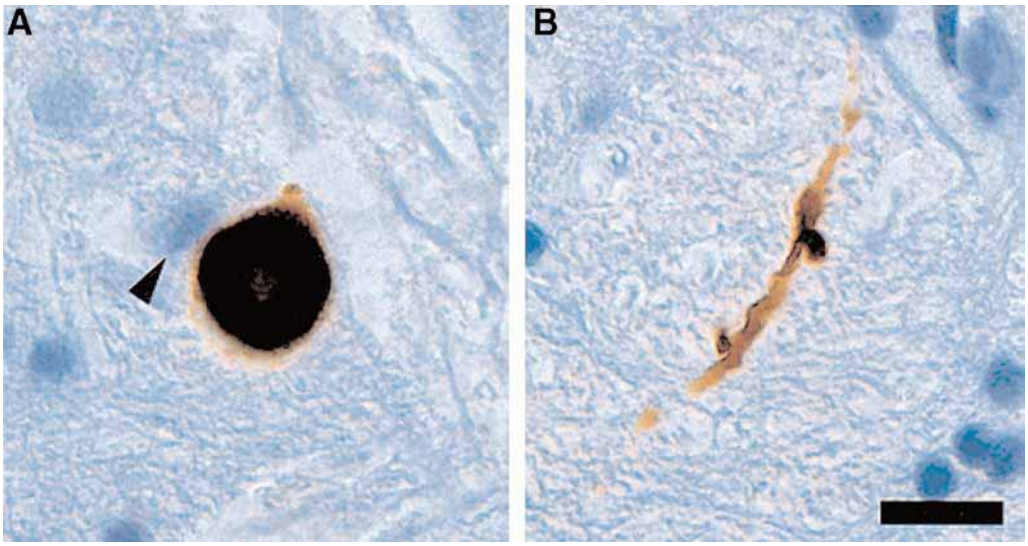

Figure 117-1 Lewy bodies and Lewy neurites are pathological hallmarks of Parkinson's disease. α-Synuclein is the main component of the intraneuronal inclusions termed Lewy bodies (LBs) and Lewy neurites (LNs). **(A)** A LB and **(B)** a LN in the substantia nigra pars compacta of a patient with Parkinson's disease stained with an antibody specific for α-synuclein. The sections were counterstained with hematoxylin, and the arrowhead in **(A)** indicates the nucleus of the neuron containing a LB. Scale bar = 20 μm.

bradykinesia and rigidity. Involvement of other neuronal systems may be responsible for cognitive, behavioral, and autonomic symptoms, although definitive clinicopathological correlations have not yet been made.

NEUROPHYSIOLOGICAL BASIS OF MOTOR IMPAIRMENT

To understand how loss of nigral dopaminergic neurons and striatal dopamine deficiency result in the motor impairments of PD, a discussion of the basal ganglia and its connections to other brain regions follows (Fig. 117-2). The term "basal ganglia" refers to a set of subcortical nuclei (including the striatum, globus pallidus, and subthalamic nucleus [STN]) that are functionally important in coordinating motor functions via connections with other regions of the brain, including the SN, thalamus, and cerebral cortex. The main region of the basal ganglia receiving input from motor cortex is the striatum. The striatum influences both the output nucleus of the basal ganglia (the internal segment of the globus pallidus [GPi]) and the substantia nigra pars reticulata (SNpr) via direct and indirect connections. The GPi and SNpr, in turn, make connections with the motor nuclei of the thalamus, which contains efferents projecting to the motor cortex, completing the so-called "motor loop."

Dopaminergic neurotransmission from the SNpc influences the so-called "direct" and "indirect" pathways that emanate from the striatum. The direct pathway consists of inhibitory connections from the striatum directly to the GPi and SNpr. The indirect pathway, however, consists of two sequential inhibitory connections, one from the striatum to the external segment of the globus pallidus (GPe) and the second from the GPe to the STN, followed by excitatory connections from the STN to the GPi and SNpr. Therefore, the net effect of connections within the indirect pathway is excitation of the GPi and SNpr.

Dopamine has opposite effects on the direct and indirect pathways because of the different types of dopamine receptors expressed in subpopulations of neurons in the striatum. D1 type receptors are expressed in striatal neurons signaling through the direct pathway, and D2 type receptors are expressed in striatal neurons that initiate the indirect pathway. Normally, neurons expressing D1 type receptors are activated by dopamine, leading to activation of the direct pathway, whereas neurons with D2 type receptors are inhibited by dopamine, leading to inhibition of the indirect pathway. Thus, dopaminergic transmission has a normal inhibitory effect on activity of the GPi and SNpr, leading to normal motor control (Fig. 117-2A).

The dopamine-deficiency state in PD, however, is associated with abnormally elevated activity of the GPi and SNpr, which underlies the motor impairments of PD. The decreased signaling through striatal D1 and D2 receptors in PD leads to a decrease in the inhibitory activity of the direct pathway and increased excitation via the indirect pathway. The characteristic loss of SNpc neurons in PD, therefore, ultimately leads to overactivity of the GPi and SNpr, resulting in excessive inhibition of thalamic nuclei and dysfunctional motor control (Fig. 117-2B).

Although the earlier discussion of the cortico-basal ganglia-thalamo-cortical motor loop is simplified and does not account for all connections between basal ganglia nuclei, it serves as a basic framework for understanding PD treatments. Because dopamine deficiency appears to be instrumental in the motor phenotype of PD, the main therapeutic strategy is dopamine replacement. L-DOPA, a dopamine precursor used routinely in PD treatment for several decades, remains the most efficacious treatment available. Its main drawback is that with increasing duration of treatment, patients develop motor complications, including dyskinesias and fluctuations in L-DOPA response. Within 5 yr of treatment, up to 80% of patients develop dyskinesias, abnormal purposeless movements and abnormal sustained muscle contractions. Because of this potential for debilitating motor complications, dopamine agonists are often used as alternative or ancillary treatment to L-DOPA. Although dopamine agonist therapy may result in a lower incidence of complications, it is also less effective in treating PD's motor symptoms.

The understanding of the neuroanatomic basis of the motor symptoms of PD serves as the basis for therapeutic neurosurgical

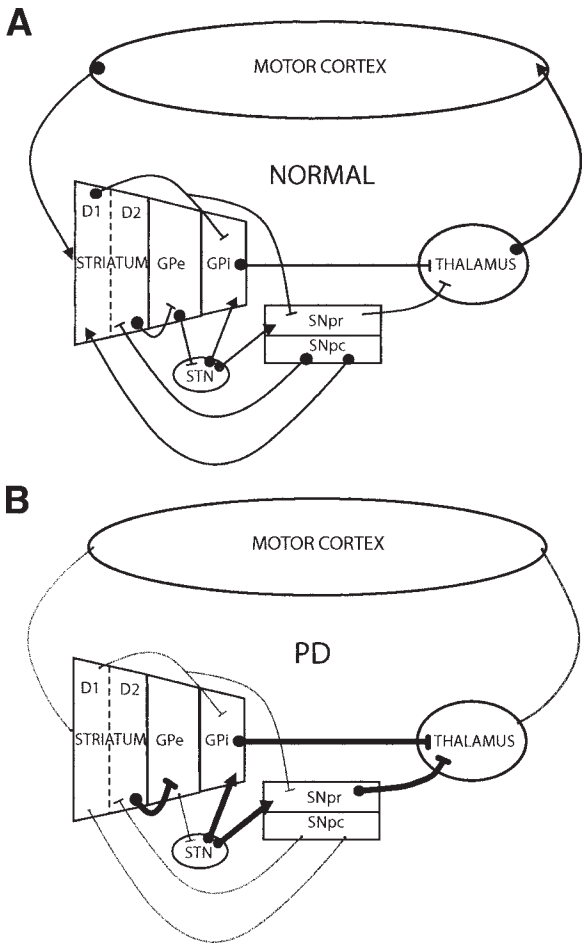

Figure 117-2 Simplified schematic of the "motor loop" under normal conditions and in Parkinson's disease. The excitatory and inhibitory connections between the components of the cortico-basal ganglia-thalamo-cortical motor loop are depicted (see text for details). **(A)** Under normal conditions, neurotransmission within the motor loop results in appropriate motor control. **(B)** In Parkinson's disease, loss of SNpc neurons causes dopamine deficiency in the striatum, leading to increased inhibitory transmission to the motor nuclei of the thalamus from the GPi and SNpr. The dysfunction of these pathways is a major contributor to the loss of motor control in Parkinson's disease. Thicker lines represent increased transmission within pathways whereas thinner lines indicated decreased transmission. Note that this schematic omits other existing connections within depicted brain regions for the sake of simplicity. D1, type-D1 dopamine receptors; D2, type-D2 dopamine receptors; GPe, external segment of globus pallidus; GPi, internal segment of globus pallidus; SNpc, substantia nigra pars compacta; SNpr, substantia nigra pars reticulata; STN, subthalamic nucleus.

options. Targets of surgical procedures include the GPi or the STN. Although such treatment is far from risk-free, ablation of the GPi or STN normalizes the abnormal neuronal firing patterns associated with dopamine deficiency and thus ameliorates the motor symptoms of PD. Bilateral ablative therapies are particularly associated with a significant risk of long-term complications, so an increasingly used alternative is deep brain stimulation. It involves long-term electrical stimulation of the GPi or STN through implanted deep-brain electrodes, which allows for adjustment and reversibility of the exogenous manipulation.

Although dopamine replacement and surgical options are effective treatment, they are purely symptomatic and do not slow disease progression. Ideal treatments would be protective and/or restorative rather than simply targeting symptoms. Allo-transplantation of fetal dopaminergic neurons seems to be a promising restorative possibility but remains investigational.

PATHOGENESIS

The relative importance of environmental vs genetic factors in the pathogenesis of PD is debatable. Inconclusive results from early twin studies and the discovery of toxins capable of causing parkinsonism have favored environmental causes. Nevertheless, twin studies utilizing functional imaging to detect presymptomatic dopaminergic deficits in siblings, as well as the linkage of several genes and loci to rare familial forms of PD, have suggested that the genetic contribution to PD is significant. Although idiopathic PD most likely has a multifactorial etiology in which undefined environmental insults and genetic predisposition interact to cause disease, knowledge about the roles of individual pathogenic factors may lead to the identification of targets amenable to therapy and useful insights into the disease process.

ENVIROMENTAL FACTORS AND OXIDATIVE STRESS

MPTP and Parkinsonism In 1979, a group of young adults in California developed severe parkinsonism after intravenous use of contaminated synthetic heroin. The agent responsible for the parkinsonism was identified as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a byproduct in the synthesis of a meperidine analog. This finding lent credibility to the idea that an environmental toxin could be involved in the pathogenesis of parkinsonism. MPTP is a lipophilic molecule that readily crosses the blood-brain barrier and is enzymatically converted to 1-methyl-4-phenylpyridium (MPP^+) by monoamine oxidase type B in glia. MPP^+ is selectively taken into dopaminergic neurons via its high affinity for the dopamine transporter and exerts its toxicity through binding and inhibition of NADH ubiquinone reductase (complex I) of the mitochondrial electron transport chain. Because electron transport chain function is necessary for oxidative phosphorylation, it has been suggested that reduction in complex I activity may lead to suboptimal ATP production and subsequent negative effects on cellular functions because of energy failure. In addition, it is thought that complex I inhibition by MPP^+ exerts toxic effects on neurons via the production of reactive oxygen species that can interfere with normal cellular functions by damaging proteins, nucleic acids, and lipids. The effects of MPTP have been confirmed in animal models, including mice, cats, and primates. Nonhuman primate models develop the cardinal parkinsonian signs (tremor, bradykinesia, rigidity, and postural instability) associated with SNpc degeneration following administration of MPTP. Although the MPTP models of parkinsonism have been useful in the development and testing of symptomatic therapies for PD, they have several drawbacks, and MPTP toxicity may not truly represent idiopathic PD. Most importantly, MPTP parkinsonism occurs shortly following an acute exposure to the toxin, whereas in PD neuronal death is progressive and occurs over many years. Further, MPTP exposure results in selective degeneration of dopaminergic neurons whereas both dopaminergic and nondopaminergic neuronal death is responsible for the variety of symptoms idiopathic PD patients suffer. The absence of fibrillar inclusions resembling LBs in MPTP parkinsonism also suggests that MPTP models provide an incomplete representation of idiopathic PD, or alternatively, that idiopathic PD is the result of a distinct pathogenetic process.

Pesticides Epidemiological studies suggest that exposure to pesticides may be a risk factor for PD development. The herbicide

1,1′-dimethyl-4,4′-bipyridinium (paraquat), when injected systemically into mice, causes dose-dependent death of dopaminergic nigral neurons associated with decreased locomotor activity. Because of its structural similarity to MPP^+, paraquat may induce oxidative stress via effects on mitochondrial electron transport. Additionally, the pesticide manganese ethylenebisdithiocarbamate (or maneb) potentiates the toxic effects of paraquat on the nigrostriatal dopaminergic pathway in mice. This suggests the possibility that mixtures of environmental toxins may be pertinent to PD etiology.

The idea that pesticides increase PD risk is further supported by the finding that the compound rotenone, often used as an insecticide in vegetable gardens or to kill fish in lakes and water reservoirs, can cause a PD-like syndrome in a rat model. In this paradigm, chronic low-dose exposure to rotenone results in complex I inhibition throughout the rat brain, but nigrostriatal dopaminergic neurons selectively degenerate. Fibrillar inclusions closely resembling LBs form in nigral cell bodies, and behaviorally, hypokinesia, flexed posture, rigidity, and tremor are variably present in exposed rats. Thus, the rotenone model demonstrates that systemic complex I inhibition can recapitulate key PD features. This rat model, however, is limited because greater than 50% of rotenone-exposed rats develop the pathological and clinical PD-like features.

Oxidative Stress in Idiopathic PD Subsequent to the discovery of MPTP's mode of action, it was found that idiopathic PD patients exhibit reduced mitochondrial complex I activity in the brain and peripheral tissues. This has led to the hypothesis that mitochondrial dysfunction and the resultant oxidative stress may play a role in the selective degeneration of vulnerable neurons in PD. Oxidative injury occurs when the antioxidant capacity of neurons is overwhelmed by the production of destructive reactive oxygen species. Complex I inhibition leads to the production of superoxide radicals, which can react with nitric oxide to form peroxynitrite. Peroxynitrite, which readily modifies native tyrosine residues in proteins to form 3-nitrotyrosine, may be a critical oxidant, as 3-nitrotyrosine is increased in PD brains and a subset of α-synuclein (the main component of LBs and LNs, *see* Implicated Genes) in PD inclusions is nitrated. Dopaminergic neurons may be particularly vulnerable to oxidative stress because the degradation of dopamine by monoamine oxidase produces hydrogen peroxide (H_2O_2), which can be converted to hydroxyl radicals that can damage cellular constituents.

IMPLICATED GENES Although most PD research focused on possible environmental factors involved in the pathogenesis of PD, the discovery of mutations in several different genes (*α-synuclein*, *parkin*, *ubiquitin C-terminal hydrolase* [UCH]-*L1*, *DJ-1*, and *NR4A2/NURR1*, *PINK1*, *LRRK2*, and *synphilin-1*), and additional loci with unidentified genes, involved in familial forms of PD has shifted much attention to the role of genetic factors. Although familial forms of PD are rare compared with idiopathic PD, research has focused on these genes with the hope that understanding rare forms of PD will yield insights into the pathogenesis of idiopathic PD.

α-Synuclein α-synuclein is a 140 amino acid residue neuronal cytoplasmic protein predominantly localized to presynaptic terminals in the CNS and loosely associated with synaptic vesicles. Its normal function remains unclear, although studies in songbirds suggest it may play a role in synaptic plasticity, and results from knockout mice indicate that it may be involved in activity-dependent negative regulation of dopamine neurotransmission. Two seminal findings clearly linked α-synuclein to PD: the discovery that point mutations in the α-synuclein gene are causative of familial forms of PD, and the demonstration that α-synuclein is the major component of LBs and LNs in familial forms of PD and in idiopathic PD.

Three missense mutations in the *α-synuclein* gene, as well as triplication of the locus containing the *α-synuclein* gene, have been identified in familial forms of PD. One of the missense mutations, resulting in the substitution of threonine for alanine at amino acid position 53 (A53T), causes autosomal-dominantly inherited PD in several families of Greek and Italian origin that are thought to have a common founder. Several clinical features may distinguish patients with the A53T mutation from those with idiopathic PD, including slightly earlier onset (mean age of onset is 46 yr), more rapid disease progression, lower prevalence of tremor, and noncardinal features such as dementia and myoclonus earlier in the disease course. A second mutation in α-synuclein (A30P) has been found in one German family, in which the autosomal-dominantly inherited PD clinically resembles idiopathic PD. Although no neuropathological reports on patients with the A30P mutation have been reported, postmortem examination of A53T brains revealed SNpc degeneration and an abundance of LBs and LNs.

More recently, a third mutation in α-synuclein (E46K) was found in a Spanish family with autosomal-dominant inheritance of PD. Interestingly, this family exhibits the clinical features of dementia and visual hallucinations in addition to parkinsonism, and neuropathologically, LBs were present in neurons of the SN as well as the cortex. Finally, the finding in an Iowa kindred that triplication of the α-synuclein gene locus can cause autosomal-dominant PD implicates gene dosage effects in the pathogenesis of PD. Neuropathological analysis of patients from this kindred has revealed extensive LB pathology.

Immunohistochemical studies show that antibodies to α-synuclein intensely stain LBs and LNs in PD as well as in other neurodegenerative disorders, such as dementia with LBs, suggesting that aggregation of *α-synuclein* may be a key event in the process of neurodegeneration. Furthermore, it is known that α-synuclein is the major building block of LBs, as immunoelectron microscopic studies have indicated that LB filaments specifically react with α-synuclein antibodies, and α-synuclein filaments assembled in vitro from recombinant protein closely resemble those in pathological inclusions. The A53T mutation accelerates fibril formation in the test tube, suggesting that accelerated polymerization of α-synuclein may be responsible for disease in patients harboring this mutation. Many other factors and events have been reported to influence the fibrillogenesis of α-synuclein in vitro, and these could be involved in the formation of α-synuclein inclusions in sporadic PD. Post-translational modification of α-synuclein (such as C-terminal truncation and phosphorylation), incubation with metals (such as aluminum, copper, and iron), and oxidative challenge (hydrogen peroxide) may accelerate fibril formation. A30P α-synuclein has been reported to bind poorly to vesicles compared with the wild-type protein, although it is not clear how this is related to disease because the autosomal-dominant mode of inheritance suggests a gain of toxic function for α-synuclein. One possibility is that impaired binding of A30P α-synuclein to vesicles hinders axonal transport of the protein, leading to accumulation of and aggregation of α-synuclein in cell bodies and processes.

Several α-synuclein animal models have been reported. Expression of wildtype and mutant α-synuclein using promoters in mice has yielded differing results. Use of the platelet-derived

growth factor promoter to overexpress wild-type α-synuclein results in a mild motor phenotype associated with dopaminergic nerve terminal loss in the striatum and inclusion formation in the SN, cortex, and hippocampus. Although these inclusions contain α-synuclein and ubiquitin, they are unlike the LBs of PD because they are granular rather than fibrillar, and some inclusions are nuclear. Expression of wildtype or mutant forms of α-synuclein by the Thy1 promoter also results in a mild motor phenotype with nonfilamentous accumulation of α-synuclein in various brain regions. Surprisingly, no differences between mice expressing wildtype and mutant forms occur. Mice expressing A53T α-synuclein under control of the mouse PrP promoter, however, develop filamentous α-synuclein inclusions, primarily in brainstem and spinal cord, which correlate with the expression of a severe, complex motor phenotype leading to paralysis and death. Although these mice have provided a model that exhibits α-synuclein inclusion formation and associated neuronal dysfunction, the SN of these mice is unaffected. Therefore, transgenic mice models have failed to provide a compelling model that recapitulates the major neurodegenerative features of PD. Results from transgenic *Drosophila*, however, may be more promising. Pan-neuronal overexpression of wildtype or mutant α-synuclein resulted in age-dependent degeneration of a subset of dopaminergic neurons, formation of filamentous α-synuclein inclusions, and locomotor dysfunction. Thus, this model exhibits key features of PD and may serve as a powerful tool in the discovery of genetic factors or pharmacological agents that influence the pathogenic process.

Parkin A number of missense, nonsense, and exon deletion mutations in the *parkin* gene can cause autosomal-recessive juvenile parkinsonism (AR-JP). Although rare in comparison to idiopathic PD, it is thought that *parkin* mutations are responsible for approx 50% of autosomal-recessively inherited parkinsonism in families in which at least one patient exhibited onset before 45 yr of age. In addition to early age of onset, AR-JP sometimes may be distinguished clinically from idiopathic PD by its slow progression and presence of features such as benefit from sleep and foot dystonia. Although AR-JP patients show good initial response to L-DOPA, they are more prone to the development of dyskinesias as a side effect of therapy. A limited number of cases in which *parkin* mutations are responsible for disease have been examined postmortem. A constant finding is loss of dopaminergic neurons in the SN, and LBs have not been found in most cases. LBs were, however, described in one patient with compound heterozygous mutations in parkin. The lack of LBs may reflect the loss of functional parkin activity in the brains of AR-JP patients. The finding that one case did show LBs, however, suggests that LBs may form early on in disease, but may not be found at autopsy because of the passage of many decades between onset and death in *parkin* cases, although this is speculative. Alternatively, the pathogenic process in *parkin* cases may be distinct from idiopathic PD. If this is the case, the compound heterozygous patient with LBs may have been affected by more than one disease process.

Parkin is a 465 amino acid residue protein that contains a ubiquitin-like domain at its N-terminal end and two RING (Really Interesting New Gene) motifs in its C-terminal half. The presence of these motifs initially suggested involvement in the process of ubiquitination, in which enzymes known as E3 ligases participate in the covalent conjugation of one or more molecules of a small protein called ubiquitin to selective lysine residues in intracellular proteins. Such tagging with ubiquitin can serve as a signal for proteasomal degradation as well as for other functions in the cell. Parkin has the ability to function as an E3 ligase, and several possible substrates have been identified, including parkin-associated endothelin-like receptor (PAEL-R), cdc-rel1, synphilin, cyclin E, a putative glycosylated form of α-synuclein, and tubulin. Thus, parkin may be a multifunctional E3 ligase involved in the clearance of many different proteins. A possible explanation for the development of AR-JP is that parkin function may be critical in the clearance of abnormal proteins that are toxic to dopaminergic neurons. For example, in cell culture, parkin suppresses the endoplasmic reticulum-stress related toxicity associated with overexpression of PAEL-R, presumably through polyubiquitination and proteasomal degradation of this misfolded protein. Furthermore, overexpression of parkin in *Drosophila* engineered to panneuronally express PAEL-R mitigates the dopaminergic degeneration caused by PAEL-R. It is unknown whether PAEL-R or other putative parkin substrates are significant in the pathogenesis of idiopathic PD.

Drosophila flies in which the fly *parkin* ortholog was knocked out exhibit reduced life span and locomotor dysfunction associated with apoptotic muscle degeneration. Mitochondrial abnormalities were noted in degenerating muscle, suggesting that parkin may be involved in clearance of a protein that is important for the integrity of mitochondrial function, or alternatively that parkin itself is critical to mitochondrial function. Although the role of parkin and putative substrates in the pathogenesis of idiopathic PD remains unclear, it is possible that a normal role for parkin in the clearance of toxic proteins is compromised in PD.

UCH-L1 UCH-L1 is one member of a family of deubiquitinating enzymes that is capable of cleaving ubiquitin C-terminal adducts to serve critical functions in the cell. UCH-L1 is abundant in brain (approx 1–2% of neuronal protein), and its activity is thought to be important in regenerating free ubiquitin for utilization in subsequent rounds of ubiquitin-mediated degradation via proteasomes. An amino acid residue substitution in UCH-L1 (I93M) has been identified in two siblings from a German family exhibiting presumed autosomal-dominantly inherited PD with incomplete penetrance. The clinical phenotype resembled idiopathic PD and ages of onset in the siblings were 49 and 51 yr. Neuroradiological and neuropathological data are not available, and the I93M substitution has not been reported in other PD patients. The S18Y polymorphism in UCH-L1, however, is a protective factor against PD in some populations, lending further support to the idea that UCH-L1 might be involved in PD pathogenesis. In vitro, the I93M substitution reduces the catalytic hydrolase activity of UCH-L1 toward an artificial substrate by approx 50%. It is unclear how this may result in a dominant phenotype in patients heterozygous for the I93M, unless the presence of only approx 75% UCH-L1 activity is lower than the threshold for maintenance of normal functions in aging neurons. Perhaps a slight reduction in deubiquitinating activity can lead to inefficient protein clearance by the ubiquitin-proteasomal pathway and accumulation of abnormal protein species, which are toxic.

DJ-1 Mutations in the *DJ-1* gene were found in patients with autosomal-recessive parkinsonism. One kindred from a genetically isolated Dutch population had a large deletion removing five of seven exons in the *DJ-1* gene, whereas an L166P missense mutation was found in an Italian family. Clinically, DJ-1 parkinsonism is characterized by early age of onset, slow progression, and lasting response to L-DOPA treatment. Focal dystonia and behavioral

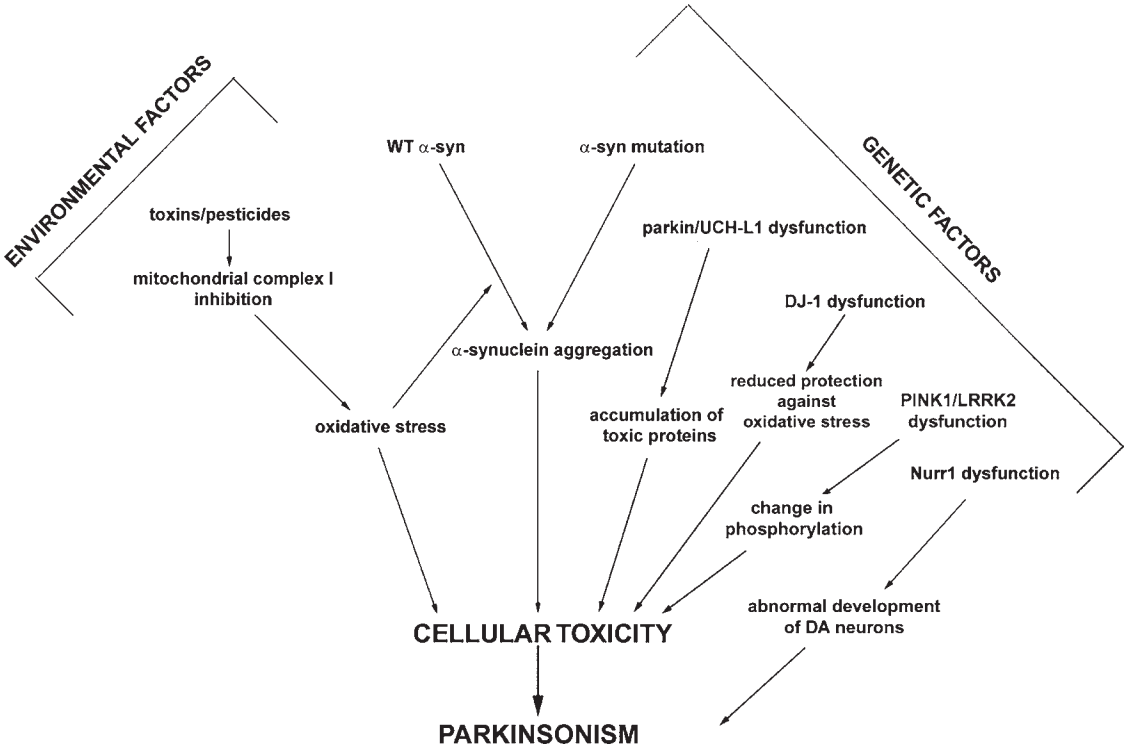

Figure 117-3 Environmental and genetic factors can contribute to the development of parkinsonism. The etiology of Parkinson's disease (PD) is thought to be multifactorial, with contributions from environmental and genetic factors. This model depicts many of the known factors that have been implicated in PD and their possible contribution(s) to PD pathogenesis. α-syn, α-synuclein; DA, dopaminergic.

disturbances have occurred in both families. Neuropathological data on patients with DJ-1 mutations have not been reported.

Although the normal function of DJ-1 is unclear, it was first identified as an oncogene, and subsequent studies suggested that it may be part of an RNA-binding protein complex. DJ-1 interacts with a protein called PIAS (protein inhibitor of activated *STAT* [signal transducer and activator of transcription protein]), which belongs to a family of ligases that covalently attach SUMO-1 (small ubiquitin-like modifier) to protein substrates, and DJ-1 itself may be sumoylated. Sumoylation (covalent attachment of SUMO to lysine residues in proteins) occurs in a number of transcription factors, suggesting that DJ-1 may have a role in transcriptional regulation. Some evidence suggests that DJ-1 may be involved in cellular responses to oxidative stress, and therefore dysfunction of DJ-1 could potentially make neurons more vulnerable to oxidative and nitrative damage. A role for any of these potential normal functions of DJ-1 remains to be explored further, as does a possible role for dysfunction of DJ-1 in the pathogenesis of PD.

NR4A2/NURR1 Another gene to be linked to familial PD is *NR4A2*, also known as *NURR1*. Previous evidence had suggested that *NR4A2* could be a genetic risk factor for PD, as *NURR1* deficient mice failed to develop dopaminergic neurons in the SN and midbrain dopaminergic neurons are more susceptible to MPTP-mediated toxicity in heterozygous mice (*NURR1* +/–). Nurr1 acts as a transcription factor thought to be important in the differentiation and maintenance of dopaminergic neurons.

Genetic screening of European individuals with familial PD has revealed two heterozygous mutations in exon 1 of *NR4A2*, upstream of the translational initiator codon of the gene. The 10 patients identified with either of these two mutations have a clinical phenotype that is similar to idiopathic PD and without atypical features, and neuropathology has not been reported in any cases. Based on studies with lymphocytes from these affected individuals, these heterozygous mutations result in a significant decrease in the levels of *NR4A2* mRNA, although the mechanism of this reduction is unclear. Further work is necessary to determine if a downregulation of *NR4A2* expression occurs in idiopathic PD and how neuronal dysfunction/degeneration may occur as a downstream consequence.

PINK1 and LRRK2 Recently, mutations in two genes whose gene products putatively function as kinases have been found in inherited forms of PD, implicating dysregulation of phosphorylation as a possible mechanism in the pathogenesis of PD. Mutations in the PTEN-induced putative kinase 1 *(PINK1)* gene are associated with an early onset autosomal-recessive form of PD characterized by typical parkinsonism but with slow progression. The encoded PINK1 protein is predicted to be a Ser/Thr protein kinase targeted to mitochondria. The autosomal-recessive inheritance suggests that loss of function of the PINK1 protein may play a role in the pathogenesis. Neuropathological data on patients with *PINK1* mutations has not yet been reported.

Furthermore, it has been discovered that mutations in the leucine-rich repeat kinase 2 *(LRRK2)* gene cause an autosomal-dominant form of PD in several families. Neuropathological analysis of patients with *LRRK2* mutations has revealed variable pathology. Although the brains of patients with *LRRK2* mutations all exhibit neuronal degeneration in the SN, some brains exhibit an absence of LB pathology, with other brains having varying degrees of LBs, LNs, and aggregates containing the microtubule-associated protein tau. As many as 5% of PD patients with a family

history and >1% of sporadic idiopathic PD patients harbor a mutation in the *LRRK2* gene, with the G2019S being the most common. Further research on the normal and abnormal forms of these presumed kinases will likely yield useful insights into molecular events which could go awry in PD.

Synphilin-1 One mutation (R621C) in the *synphilin-1* gene has been identified in two apparently independent German patients with sporadic PD. These patients had no family history of PD or other movement disorders. Whereas the significance of this finding is still unclear, synphilin-1 protein had been previously implicated in PD as it was identified as an α-synuclein interacting protein, and synphilin-1 appears to be present in a small percentage of LBs. Furthermore, studies have revealed that cotransfection of synphilin-1 and α-synuclein in cell culture results in intracellular protein deposits containing both proteins. Whereas this is an intriguing finding, how closely these aggregates resemble the LBs characteristic of PD is debatable.

CONCLUSION

Idiopathic PD likely represents a complex disease in which many factors interact in pathogenic pathways to cause disease. Clues from known environmental and genetic factors suggest roles for oxidative stress, protein aggregation, and impaired protein clearance in the pathogenesis of parkinsonism (*see* Fig. 117-3). Such events need not be mutually exclusive and may all contribute to the development of sporadic PD. As more knowledge is gained about the identity and effects of individual environmental and genetic factors, further investigation will be necessary to determine how these entities may interact to produce the neuronal dysfunction and death that underlies the phenotype of PD. Researchers have begun to pursue studies in which transgenic animals are exposed to environmental toxins. As understanding of the molecular events underlying the pathogenesis of PD improves, the development of therapeutic interventions that can potentially prevent disease initiation and/or progression will become more of a reality.

118 Genetics and Neurobiology of Alzheimer's Disease and Frontotemporal Dementias

PETER H. ST. GEORGE-HYSLOP

SUMMARY

Alzheimer's Disease (AD), Lewy body variant of AD, and the frontotemporal dementias are the three most common causes of adult onset dementia. This chapter will examine the genetic basis of AD and Lewy body variant, familial British dementia and familial encephalopathy with neuronal dementia with neuroserpin deposits, tau mutations in FTDP-17, and the practical implications of genetic testing.

Key Words: Alzheimer's disease; frontotemporal dementias; Lewy body variant of Alzheimer disease.

INTRODUCTION

Alzheimer's Disease (AD), Lewy body variant (LBV) of AD, (which is now referred to as Dementia with Lewy Bodies [DLB]) and the frontotemporal dementias (FTD) are the three commonest causes of adult onset dementia. These diseases present in mid to late adult life with progressive defects in memory and higher cognitive functions such as the performance of complex, learned motor tasks (apraxias), reasoning, and so on. The clinical features of AD and DLB (deficits in recent and immediate memory deficits, praxis, reasoning and judgment, and so on) stem from involvement of the temporal lobe, hippocampus, and the parietal association cortices, with lesser involvement of frontal lobes until late in the disease. DLB overlaps with AD, sharing most of the clinical and neuropathological features of AD, but differentiated by prominent visual hallucinations, sensitivity to phenothiazine tranquilizers, and the presence of Lewy bodies (α-synuclein containing intraneuronal inclusions) in neocortical neurons. In contrast, in FTD, the clinical syndrome is overshadowed by behavioral disturbances (disinhibition, aggressivity, and so on) and speech disturbances (aphasia), which arise from involvement of the frontal neocortex. The FTD symptom complex frequently also includes additional features such as muscle rigidity, tremor, bradykinesia (Parkinsonism), and muscle weakness (amyotrophy).

All three diseases have a characteristic set of neuropathological changes including prominent loss of neurons in selected cerebral cortical regions (e.g., hippocampus and temporoparietal neocortices in AD and DLB; frontal neocortices in FTD) (Figs. 118-1 and 118-2). In AD and DLB, the second prominent neuropathological feature is complex, extracellular, fibrillar deposits in the cortex, termed senile or amyloid plaques. These plaques contain a number of proteins including apolipoprotein E (APOE) and 1-antichymotrypsin, but the principal protein is amyloid-β (Aβ)-peptide, which is derived from proteolytic cleavage of a longer precursor β-amyloid precursor protein (APP). Finally, AD, DLB and FTD are characterized by neurofibrillary tangles, intraneuronal inclusions made up of phosphorylated forms of tau, a microtubule associated protein. These intraneuronal phosphorylated tau aggregates are also called neurofibrillary tangles. The overlap between AD and DLB is considerable in their major clinical and neuropathological features, and in their genetic bases (i.e., both show associations with the APOE ε4 variant—*see* Apolipoprotein E). As a result, the genetics of AD and DLB are discussed together.

GENETIC BASIS OF AD AND DLB

A number of genetic epidemiology studies have been undertaken on probands with AD and their families. Cumulatively, these studies strongly argue that the familial aggregation of AD is not simply because of the high frequency of AD in the general population. They reveal that the overall lifetime risk for AD in first-degree relatives of AD probands is approx 38% by age 85 yr. They also demonstrate that most cases of familially aggregated AD probably reflect a complex mode of transmission such as one or more common independent, but incompletely penetrant, single-autosomal gene defects; a multigenic trait; or a mode of transmission in which both genetic and environmental factors interact. Nevertheless, a small proportion of AD cases (approx 10%) appear to be transmitted as pure autosomal-dominant Mendelian traits with age-dependent but high penetrance. Molecular genetic studies on pedigrees with the latter type of familial AD (FAD) has led to the discovery of four different genetic loci associated with inherited susceptibility to AD. It is suspected that at least two, and possibly several additional AD susceptibility loci remain to be identified because the four known FAD loci account for only approx 50% of FAD cases.

THE AMYLOID PRECURSOR PROTEIN The first gene to be identified in association with inherited susceptibility to AD was

the β-APP gene. It encodes an alternatively spliced transcript, which, in its longest isoform, encodes a single transmembrane spanning polypeptide of 770 amino acids. The β-APP precursor protein undergoes a series of endoproteolytic cleavages (Fig. 118-3). One of these is mediated by several, membrane-associated enzyme activities (termed α-secretase), which cleave β-APP_{695} in the middle of the Aβ-peptide domain and liberate the extracellular N-terminus of β-APP. The identity of α-secretase is not known with certainty, although members of the TACE and ADAM-17 disintegrin metalloprotease family are strong candidates.

The other pathway involves sequential cleavages by β- and γ-secretases, and generates the 40–42 amino acid Aβ-peptide. The first cleavage occurs at the beginning of the Aβ-domain, and is mediated by β-secretase (BACE 1), a type-1 transmembrane glycosylated aspartyl protease, resident in post Golgi membranes and at the cell surface. The second set of cleavages occurs at residues +40, 42 by a putative enzyme activity termed γ-secretase (Fig. 118-4). (Data suggests that a concurrent cleavage may be necessary at residues +49, +50, and 51—termed ε-cleavage.) Both γ-cleavage and ε-cleavage require the presence of the presenilin proteins (*see* Presenilin1), and both cleavage events occur mainly in a post-Golgi compartment and/or following reentry of β-APP from the cell surface. The N-terminal product of γ/ε-secretase is Aβ, whereas the C-terminal product is a labile fragment termed amyloid intracellular domain, which might act as a signal transduction molecule. The γ/ε-secretase cleavage actually generates a mixture of Aβ-peptides, some containing 40 residues, the others containing 42 amino acids. Aβ-peptides ending at residue 42 (long-tailed Aβ) are thought to be more prone to form fibrils and more neurotoxic than Aβ ending at residue 40, which is the predominant isoform produced during normal metabolism of β-APP. Little is known about the physiological role (if any) of Aβ. Aβ is removed by several pathways, including degradation by neutral endopeptidase cleavage (e.g., by neprilysin) or by insulin degrading enzyme (IDE).

The function of β-APP is unknown. Knockout of the murine β-APP gene leads only to minor weight loss, decreased locomotor activity, abnormal forelimb motor activity, and nonspecific degrees of reactive gliosis in the cortex. In vitro studies in cultured cells suggest that secreted β-APP (β-APPs) can function as an autocrine factor stimulating cell proliferation and cell adhesion. Other studies have implied a role for β-APP in signal transduction by association of β-APP with heterotrimeric GTP-binding proteins, a receptor for kinesin-1 during the fast axoplasmic transport of vesicles containing BACE and presenilins, and/or a signal transduction molecule in a manner similar to the role of the Notch intracellular domain.

Several different missense mutations have been discovered in exons 16 and 17 of the β-APP gene in families with early-onset AD (Table 118-1 and http://molgen-www.uia.ac.be/ADMutations). All of these mutations either alter APP processing and Aβ-production, or alter the propensity of Aβ to aggregate into β-sheet amyloid fibrils. Some of the missense mutations in the β-APP gene result in the relative (APP_{717}) or absolute ($APP_{670/671}$) overproduction of full

length Aβ-species ending at residue 42. Other mutations cause either the production of full length $A\beta_{40}$-species (APP_{692}, APP_{693}), or the overproduction N-terminally truncated species of Aβ ending at residue 42 (APP_{715}), that have increased propensity to assemble into neurotoxic amyloid fibrils (i.e., are "amyloidogenic"). Multiple molecular mechanisms proposed to explain the neurotoxic effects of Aβ (and especially of small fibrillar aggregates of amyloid called protofibrils) include induction of apoptosis by direct effects on cell membranes and by indirect effects, such as potentiating effects of excitatory amino acids, oxidative stress, and increases in intracellular

Table 118-1
Missense Mutations in The β-APP Gene

Codon	*Mutation*	*Phenotype*
665	Gln→Asp	Late-onset AD—no segregation
670/671	Lys-Met→Asn-Leu	"Swedish" FAD; increased Ab production
673	Ala→Thr	No disease phenotype
692	Ala→Gly	"Flemish" FAD + cerebral haemorrhage; increased Ab
693	Glu→Gly	"Arctic" early-onset AD
	Glu→Gln	HCHWA-D
713	Ala→Val	Schizophrenia—no segregation
715	Val→Met	Early-onset FAD, reduce total Ab production, particularly Ab40
716	Ile→Val	FAD
717	Val→Ile	FAD; increased long Ab isoforms
	Val→Phe	FAD
	Val→Gly	FAD
723	Leu→Pro	FAD

calcium and free radicals. However, the cytoplasmic C-terminal stub (C31-β-APP) may also be toxic when overexpressed.

APOLIPOPROTEIN E The association of APOE with inherited susceptibility to AD was uncovered by the concurrence of three lines of investigation. Genetic linkage studies in pedigrees with predominantly late-onset, familially aggregated AD provided suggestive evidence ($z = +2.5$) for an AD susceptibility locus on chromosome 19q12-q13 near the APOE gene. Second, analysis of proteins from the cerebrospinal fluid that were capable of binding the Aβ-peptide revealed that one of the proteins was APOE. Finally, APOE is a component of the senile plaque of AD.

The APOE gene in humans contains three common polymorphisms: ε2 (cysteines at codon 112 and codon 158); ε3 (cysteines at codon 112); and ε3 (arginine at codon 112). Analysis of these polymorphisms in normal control populations and in patients with AD shows an increased frequency of the ε4 allele in patients with AD (allele frequency in AD is about 40%, compared with 15% in normals), and a smaller reduction in the frequency of the ε2 allele (from 10% to approx 2% in AD). More significantly, there is a dose-dependent relationship between the number of copies of ε4, and the age-of-onset of AD, such that ε4/ε4 subjects have an earlier onset than heterozygous ε4 subjects. Subjects with an ε2 allele, conversely, have a later onset. The association between ε4 and AD has been robustly confirmed in numerous studies and in several ethnic groups. The association is weaker with advanced age of onset, and the putative protective role of the ε2 allele is less clear at younger ages of onset (in which it may be associated with a more aggressive course). The association of APOE ε4 with AD has been replicated in numerous ethnic groups with the possible exception of black Americans and American Hispanics, where results are conflicting.

Although the association between APOE ε4 and AD is robust, it is not entirely specific. Observations in patients with head injury, spontaneous intracerebral hemorrhage, and in patients undergoing elective cardiac bypass surgery suggest a poorer outcome for patients with the ε4 allele. There is a confirmed association between the ε4 allele and DLB (*see* Genetic Basis of AD and DLB).

The mechanism by which the ε4 allele is associated with an earlier onset of AD, and by which the ε2 allele is associated with a later onset is unclear. The most obvious hypothesis is that APOE might influence the production, distribution, or clearance of the Aβ-peptide. This hypothesis is supported by five observations. First, the genotype at APOE modulates age-of-onset in subjects carrying the β-APP Val717Ile mutation (but not the APP_{692} mutation), suggesting a direct biochemical interaction between APOE and β-APP (or its metabolic products). Second, subjects with one or more APOE ε4 alleles have a higher Aβ-peptide plaque burden than do subjects with no ε4 alleles. Third, in vitro studies suggest that delipidated APOE ε4 binds Aβ more avidly than APOE ε3. Fourth, both APOE and Aβ are cleared through the lipoprotein-related receptor, so that APOE ε4 and Aβ compete for clearance. Finally, transgenic mice expressing

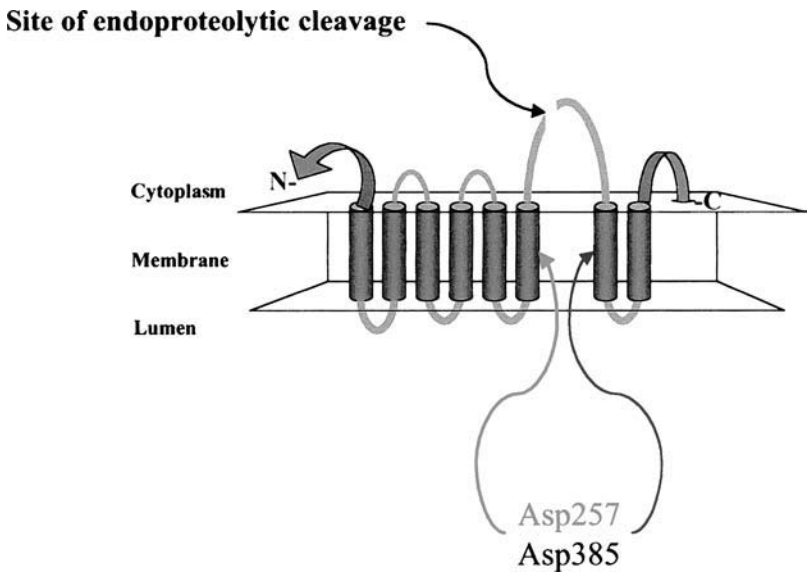

Figure 118-5 The presenilins are polytopic transmembrane proteins with at least seven transmembrane domains. The N-terminus, a hydrophylic loop between TM6 and TM7, and the C-terminus are all oriented toward the cytoplasm. There are two aspartate residues embedded in TM6 and TM7 respectively. These residues are thought to have a catalytic function. The other members of the complex (not shown) are Nicastrin, a type-1 transmembrane glycoprotein; APH-1, a polytopic transmembrane protein; and PEN-2, a small, quite hydrophobic, protein which is thought to span the membrane twice.

the β-APP_{V717F} mutation (PDAPP mice) develop profound cerebral Aβ-deposition when bred on an $APOE^{+/+}$ background, but have very little Aβ-deposition on an $APOE^{-/-}$ background.

An alternate hypothesis for the role of APOE in the genesis of AD/LBV concerns changes in cholesterol metabolism mediated by APOE that may affect APP processing. Both epidemiological and direct experimental evidence in cell culture models suggests that cholesterol metabolism and APP metabolism are functionally intertwined. Specifically, reduction in cellular cholesterol availability results in significant changes in APP trafficking and processing, with the resultant reduction in Aβ-formation. Additional support for a link between APOE, cholesterol and Aβ comes from the observation that patients who have taken statins for hypercholesterolemia appear to have a reduced incidence of AD.

Finally, it has been suggested that APOE may be involved in synaptic plasticity during regeneration and repair, and that the ε4 allele is less efficient in this role. This idea is in accord with clinical epidemiological data suggesting that the presence of APOEε4 is associated with a poorer outcome after a variety of unrelated central nervous system injuries including head injury, stroke, and coronary artery bypass grafting. Thus, the association between APOE ε4 and AD may not determine whether AD occurs, but rather, the clinicopathological response to other causative factors. Indeed, these putative effects of APOE on several different mechanisms need not be mutually exclusive.

PRESENILIN 1 Genetic mapping studies located a third Alzheimer susceptibility locus (AD3) to a region of approx 10 cM on the long arm of chromosome 14. The actual disease gene, presenilin 1 (PS1), was isolated using a positional cloning strategy.

The PS1 gene is highly conserved in evolution, being present in *Caenorhabditis elegans* and *Drosophila melanogaster*. PS1 encodes an integral membrane protein. Favored models have 8 transmembrane domains, with a large, hydrophillic, acid-charged loop domain between the putative sixth and seventh transmembrane domains. The PS1 protein is approx 50 kDa in size and is predominantly located within cellular membranes in the endoplasmic reticulum, the perinuclear envelope, the Golgi apparatus and at the cell surface, as well as in some uncharacterized intracytoplasmic vesicles. Only very small amounts of the PS1 holoprotein exist within the cell at any time. Instead, the holoprotein undergoes endoproteolytic cleavage within the TM6–TM7 loop domain (Fig. 118-5). The biologically active form of the presenilins are the N- and C-terminal fragments, which are tightly associated with each other in a high molecular weight, intracellular protein complex (>450 kDa). This protein complex coelutes with γ-secretase activity in cellular fractionation studies. Several other protein components of the presenilin complexes have been identified, including nicastrin (~110 kDa type-1 transmembrane glycoprotein); APH-1 (a polytopic transmembrane protein that may act as the initial assembly molecule for the complex); and PEN-2 (a short hydrophobic protein with two transmembrane domains, but with unknown function).

The presenilins play either a direct catalytic or an indirect (facilitatory) role in the proteolytic processing ("regulated intramembranous proteolysis") of several type-1 transmembrane proteins including APP, p75, LRP, ErbB4, and Notch. Null mutations in PS1 (or any of the other presenilin complex components) result in cessation of γ- and ε-secretase cleavage of these proteins (Fig. 118-6). Loss of Notch cleavage results in severe developmental defects, which directly arise from the failure to generate the Notch intracellular domain. Loss of γ- and ε-cleavage of APP causes a profound reduction in the secretion of Aβ and the accumulation of the substrate for γ/ε- cleavage (i.e., C83-APP [α-stubs] and C99 [β-stubs], which are the derivatives of α- and β-secretase cleavage, respectively). It is unclear whether the presenilins just have a direct enzymatic activity, or whether they are also indirectly involved perhaps through modulating trafficking and/or activation of various substrates or other components of the γ-secretase complex.

More than 128 different mutations have been discovered in the PS1 gene (Table 118-2 and http://molgen-www.uia.ac.be/ADMutations). Most of these mutations are missense mutations

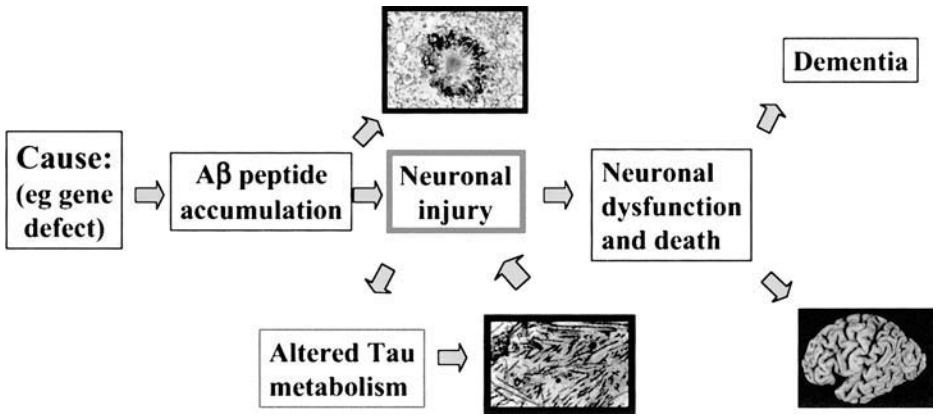

Figure 118-6 Schematic for the putative "amyloid cascade" in which accumulation of neurotoxic Aβ initiates a series of downstream events, some of which are also neurotoxic themselves (e.g., misprocessing and accumulation of tau).

giving rise to the substitution of a single amino acid. A few in-frame splicing, deletion or insertion defects have also been identified. However, nonsense mutations resulting in truncated proteins, which would cause loss-of-function mutations, have yet to be found in AD-affected subjects.

All of the PS1 mutations associated with AD increase γ-secretase cleavage of β-APP and preferentially increase the production of toxic long-tailed Aβ-peptides ending at residue 42. However, some investigators think that like the β-APP mutations, PS1 and presenilin 2 (PS2) mutations may also cause neurodegeneration by modulating cellular sensitivity to apoptosis induced by a variety of factors, including Aβ-peptide.

PRESENILIN 2 During the cloning of the PS1 gene on chromosome 14, an homologous sequence, PS2**,** was identified on chromosome 1. PS2 encodes a polypeptide whose open reading frame contains 448 amino acids, with substantial sequence similarity to PS1 (overall identity approx 60%), and a similar structural organization. Despite this similarity, PS1 and PS2 are likely to have distinct but overlapping functions. For instance, PS2 does not functionally repair either the APP or Notch processing defects in $PS1^{-/-}$ animals, yet PS2 mutations, like PS1 mutations, increase the secretion of long-tailed Aβ-peptides.

Mutational analyses have uncovered a small number of missense mutations (approx 9) in the PS2 gene in families segregating early-onset forms of AD (http://molgen-www.uia.ac.be/ADMutations). The phenotype associated with PS2 mutations is much more variable. Thus, the majority of heterozygous carriers of missense mutations in the β-APP and PS1 genes develop the illness between ages 35 and 55 yr for PS1 mutations, and between 45 and 65 yr for β-APP mutations. In contrast, the range of age-of-onset in heterozygous carriers of PS2 mutations is between 40 and 85 yr, and there is at least one instance of apparent nonpenetrance in an asymptomatic octogenarian transmitting the disease to affected offspring. Furthermore, in contrast to APP mutations, the effect of APOEε4 on the age-at-onset in PS2 mutations is either absent or less profound. Modifier loci other than APOE probably account for much of this variation.

OTHER GENES FOR AD Large surveys of patients with familial AD indicate that the APP, APOE, PS1, and PS2 genes account for about half of the genetic risk factors for AD. It is therefore likely that there are several additional AD susceptibility genes. Some of these loci will be associated with additional rare, but highly penetrant defects similar to those seen with mutations in PS1 and APP. Other genes may result in incompletely penetrant

autosomal-dominant traits like those associated with PS2. However, it is likely that a significant proportion of the remaining genes will have low-effect sizes similar to APOE, and in which the ultimate phenotype is likely to be influenced by the presence or absence of other genetic and environmental risk factors.

Multiple strategies have been deployed to map these additional AD susceptibility genes. Genetic linkage studies and family based association analyses have been employed on datasets with pedigrees multiply affected with AD, and have led to the suggestion that additional susceptibility loci may exist in the pericentromeric region of chromosome 12 and the long arm and pericentromeric region of chromosome 10. However, the genes in these regions that cause susceptibility to AD have not been identified.

A second strategy to identify AD genes has been to use cohorts of sporadic AD cases and age/sex-matched controls in a case-control association design. This has led to a long list of potential candidate genes, most of which have not been robustly replicated. A partial list of candidate genes provisionally identified as putative AD susceptibility loci includes α1-chymotrypsin, very low density lipoprotein receptor, low-density lipoprotein receptor related protein, butyrylcholinesterase, bleomycin hydroxylase; IL4, and so on. However, in contrast to APOE ε4, most of these candidate genes have not received widespread confirmation when tested in independent but comparable datasets. A number of obvious candidate genes involved in APP processing, including BACE (β-secretase involved in Aβ generation), neprilysin and insulin degrading enzyme (involved in Aβ-degradation) have been screened, but have not been widely found to have genetic variants associated with increased risk for AD.

FAMILIAL BRITISH DEMENTIA AND FAMILIAL ENCEPHALOPATHY WITH NEURONAL DEMENTIA WITH NEUROSERPIN DEPOSITS

Two very rare forms of inherited dementia—familial British dementia and familial encephalopathy with neuroserpin inclusions (FEN1b)—have been described that support the emerging concept that many inherited dementias are disorders of protein processing in which there is intracellular or extracellular accumulation of toxic misfolded/misprocessed proteins—a theme common to all the diseases discussed here.

Familial British dementia is characterized by spasticity, ataxia, and progressive dementia accompanied by widespread demyelination and distinctive perivascular fibrous deposits. A T→A transversion mutation in the stop codon of the BRI gene on chr 13 causes the addition of several amino acids at the C-terminus of the BRI protein. Although the normal function of the BRI protein is unknown, the presence of the extra C-terminal amino acids causes the protein to be misprocessed by a furin-mediated cleavage. This results in the accumulation of a 34 amino acid C-terminal derivative (the ABRI peptide) that assembles into toxic amyloid deposits through mechanisms yet to be elucidated.

Missense mutations in Neuroserpin, a neuron specific serine protease inhibitor (serpin), have been described in two pedigrees with a familial dementia. In these families with FEN1B, the mutant neuroserpin forms typical serpin loop-sheet polymers that assemble into fibrous aggregates, which appear as 5–50 μm PAS-positive eosinophilic inclusions, called "Collins bodies," in the deep layers of the cerebral cortex, subcortical nuclei, and substantia nigra.

FRONTOTEMPORAL LOBE DEMENTIA FTD is a pleomorphic neurodegenerative illness that typically begins before age 65. In a minority of cases, the disease is inherited as an autosomal-dominant trait. FTD often begins with personality and behavioral changes including disinhibition manifest by alcoholism, hyperreligiosity, hypersexuality, hyperphagia (elements of the Kluver-Bucy syndrome) and stealing. As the disease progresses, further abnormalities in judgment, language, and praxia develop. In addition to these cognitive changes, some patients also developed Parkinsonism and amyotrophy, and presentations with primary progressive aphasia, dystonia, and/or oculomotor disturbances are not infrequent. Neuropathologically, the illness is typified by frontotemporal atrophy with severe neuronal loss, spongiform change in the superficial layers of the neocortex of the temporal lobe and frontal cortex, neuronal loss, and gliosis in the substantia nigra and amygdala, and anterior horn cell loss in the spinal cord. In some cases, notably those arising from mutations in the tau gene (*see* Tau Mutations in FTDP-17) the other prominent neuropathological feature is the presence of tau fibrils in neurons and/or glia.

Genetic linkage studies in the subset of FTD cases showing autosomal-dominant inheritance revealed that 10–40% of these familial FTD cases showed genetic linkage to DNA markers on chromosome 17 near the tau gene (*see* Tau Mutations in FTDP-17). It was also apparent that a significant proportion of autosomal-dominant FTD pedigrees did not show linkage to this region. Genetic linkage studies in these cases subsequently led to the discovery of an additional, but uncloned genetic locus associated with autosomal-dominant FTD with amyotrophic lateral sclerosis on chromosome 9q. Other loci are expected to exist.

TAU MUTATIONS IN FTDP-17

Sequencing of the tau gene led to the discovery of several different mutations in some families with FTDP-17. Tau is an abundant phosphoprotein predominantly expressed in both central and peripheral nervous systems. In brain it is found predominantly in axons of neurons, with lower levels in some glial cells. The major physiological function of Tau is to bind to and stabilize microtubules, and it may play a role in microtubule-dependent axoplasmic transport. Microtubule binding is mediated by three or four "microtubule-binding domain" repeats (depending on alternative splicing of the tau mRNA); these isoforms are therefore known as 3-repeat or 4-repeat isoforms.

Tau phosphorylation is developmentally regulated. Phosphorylation is thought to be regulated by one or more of several kinases including mitogen-activated protein kinase, glycogen synthase kinase-3, neuronal cdc2-like kinase and stress-activated protein kinases. The phosphorylation state of tau is balanced by the dephosphorylating activity of protein phosphatase 2A. Hyperphosphorylation is an invariant feature of the filamentous tau deposits that characterize a number of neurodegenerative diseases including AD and FTD.

Tau mutations causing FTDP-17 have generally been missense and deletion mutations in the coding region or intronic mutations located close to the 5′-splice site of the intron following exon 10. The tau missense mutations have generally been located in the microtubule-binding repeat region or close to it. Most of these missense mutations reduce the ability of tau to interact with microtubules, as reflected by a marked reduction in the ability of mutated tau proteins to promote microtubule assembly. Intronic

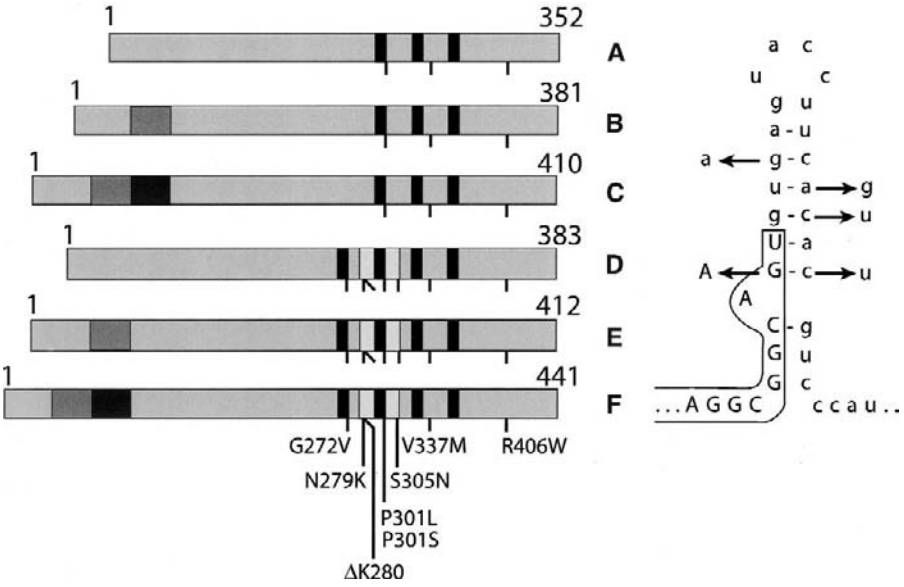

Figure 118-7 Diagram of the various splice forms of tau showing three microtubule repeat binding domains and four microtubule binding domains. The site of some of the mutations causing FTDP-17 is depicted.

mutations are located at positions +3, +13, +14, and +16, relative to the first nucleotide of the splice-donor site of the intron following exon 10. These intronic mutations disrupt an RNA stem-loop structure at the exon 10/5′-intron boundary and lead to increased production of transcripts encoding exon 10, which is reflected by a net overproduction of tau isoforms containing four rather than three microtubule binding repeats.

Validation of the hypothesis that overexpression of wild-type tau with four microtubule binding repeats or overexpression of mutant tau can cause intracellular accumulation of fibrillar deposits of tau and neurodegeneration has been obtained from the analysis of transgenic mice. Overexpression of either wild-type four repeat tau, or of P301L mutant tau transgenes results in neurodegeneration with NFT and spheroids particularly in the amygdala, brainstem, and cerebellar nuclei, and spinal cord. These neuropathological changes were associated with hindlimb weakness, amyo-trophy, and dystonic posturing.

The mechanism by which tau mutations or overexpression of specific isoforms of tau, cause neurodegeneration is unclear. There is some evidence that they alter the binding of tau to microtubules, causing increased amounts of free tau, which then inhibits kinesin-dependent intracellular transport of organelles, neurofilaments and cargo vesicles (including those carrying APP).

Cross breeding transgenic mice overexpressing mutant human tau transgenes with transgenic mice expressing mutant APP transgenes, and giving intracerebral injections of Aβ42 into these tau mice has resulted in a modest exacerbation of the tau pathology. This supports the idea that defects in APP processing in AD may initiate a cascade of other events (Fig. 118-7), which add to the neurotoxic cascade (i.e., tau misprocessing) and lead to neurodegeneration. If correct, this brings together the final common pathways for several neurodegenerative diseases.

PRACTICAL IMPLICATIONS: GENETIC TESTING

The discovery that mutations in specific genes are associated with inheritable susceptibility to AD and FTD, together with increasing public awareness of genetics as a cause of illness, and of familial aggregation of these diseases in particular, has led to the frequent need for physicians to consider the merits of genetic counselling and genetic testing. In the absence of clearly effective preventative or curative treatments without significant side effects, the main reason for genetic counselling and testing is currently to provide information only. However, although such information can be empowering, it also has the potential to be misused to the patient's disadvantage.

There is relatively little practical experience with genetic counselling of members of families multiply affected with AD or FTD. Consequently, most of the paradigms for genetic counselling of members of AD families are based on similar paradigms used in the counselling of subjects with Huntington's disease. The Huntington's disease model is useful for counselling of members of families with early-onset FAD or FTD because the age-of-onset is often similar (30–65 yr of age) and has a similar pattern of transmission (highly penetrant, age-dependent penetrance, autosomal-dominant segregation). Thus, it is possible to screen at-risk family members for the presence of mutations detected in affected individuals, and to counsel these family members based on the concept that β-APP, PS1 and tau mutations are highly penetrant (approx 95%) with typical age-of-symptom-onset between 35 and 65 yr. PS2 mutations on the other hand have a lower penetrance and a more variable age-of-onset (45–85 yr). Using the Huntington's disease paradigm, members of a small number of families with PS1 and β-APP mutations have been counselled without significant problems. Screening for PS1 mutations is cost effective when done on symptomatic cases with a positive family history of AD and onset before the age of 60 yr.

Although use of the Huntington's disease paradigm will probably work well for PS1, PS2, and β-APP mutations, mutations in these genes are a comparatively rare cause of FAD, cumulatively accounting for approx 50% of early-onset FAD (which itself accounts for approx 5% of all AD). A much more common clinical experience is the presence of two or three affected family members

with late-onset AD in a small nuclear pedigree. Frequently, in these "multiplex" late-onset AD pedigrees, the disease does not inherit as a classic autosomal-dominant trait. As a result, in any given family, it is frequently unclear whether the multiplex pedigree structure reflects an incompletely penetrant autosomal-dominant trait, or a more complex mode of transmission involving either the additive effects of several genes or the interaction of genes and environment. Empirical counselling of pedigrees of this type is difficult and must largely be based on epidemiological studies. Although the use of molecular genetic studies would clearly facilitate counselling in such pedigrees, the only locus that has shown robust association with late-onset AD is the APOE gene. Retrospective studies, in autopsy and clinical series, have suggested that the cumulative lifetime risk for AD in subjects homozygous for APOE ε4 may be as high as 90% by age 90 yr. However, even from these retrospective studies, it is apparent that there is a huge variation in the age-of-onset of AD even in subjects who are homozygous for APOE ε4 (50–90 yr). To confound matters further, a small number of limited prospective studies suggest that the APOE genotype is a relatively poor predictor of the onset of AD even in high-risk groups such as those with age-associated memory loss. Consequently, a number of research groups have recommended that the APOE genotype not be used for presymptomatic testing. The question of whether the APOE genotype may be of assistance in establishing the diagnosis of AD in demented patients undergoing diagnostic workup is under discussion. Most experts agree that although the APOE genotype studies might form a part of the diagnostic armamentarium, they are unlikely by themselves to be the only test that should be done even in individuals with classic clinical features of AD.

It is likely that additional AD and FTD susceptibility genes will be identified. However, until most or all of these genes are identified, and their relative frequencies as a cause of dementia in specific populations can be defined, genetic testing of at-risk family members can only be reasonably performed if there is a testable, clinically affected member available. If an affected pedigree member is available, their DNA can be screened for mutations in the known susceptibility genes. If mutations are found, this information can be used for testing at-risk family members. Where no mutations in the affected subject's DNA are found, it can be reasonably assumed that the disease is caused by mutations or polymorphisms in other genes yet to be identified, and mutation screening studies in at-risk family members would not be indicated. However, in the absence of a living affected member who can be tested, the screening for mutations in the DNA of at-risk family members is likely to be unproductive because the failure to discover disease-related polymorphisms or mutations in the known AD or FTD genes can give no reassurance that the at-risk family member is not a carrier of a mutation in another susceptibility gene.

119 Prion Diseases

ADRIANO AGUZZI

SUMMARY

Considerable experimental and theoretical evidence supports the proposition that the prion (i.e., the transmissible entity of transmissible spongiform encephalopathies) is made up of a self-propagating isoform of PrP, and that informational nucleic acids are not required for transmissibility. Many questions still need to be elucidated, such as the mechanism and the requirements for the conversion reaction, the portals of entry of prions into the body, the transport of prions from periphery to CNS, and the mechanism of pathogenesis. Clinically, early diagnosis of prion disease and treatments aiming to arrest or cure prion disease in humans are important goals.

Key Words: Bovine prion disease; central nervous system; Creutzfeldt-Jakob disease; fatal familial insomnia; Gerstmann-Sträussler-Scheinker; transmissible spongiform encephalopathies.

INTRODUCTION

Prion diseases, or transmissible spongiform encephalopathies (TSEs), are CNS degenerative disorders of sporadic, familial, or acquired nature. They include Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker (GSS) syndrome, Kuru, and fatal familial insomnia (FFI) in humans, and a number of encephalopathies of animals. The latter comprise scrapie of sheep, bovine spongiform encephalopathy (BSE) or "mad cow disease," chronic wasting diseases of deer and elk, and similar diseases of exotic ungulates. A large body of circumstantial evidence has accumulated indicating that BSE prions can provoke a variant form of CJD in humans. This chapter describes the nature of the infectious agent along with its molecular and biochemical properties, and gives a synopsis on clinical, histopathological, and genetic features of TSEs.

The TSEs, or prion diseases (Table 119-1), represent a group of diseases with unique clinical and histological features, the transmission of which can be genetic or infectious. According to most available evidence, the agent causing TSEs, termed prion, is devoid of informational nucleic acids and consists of an "infectious" protein capable of converting a normal host protein called PrP^{C}, PrP-sen, or simply PrP, into a likeness of itself (called PrP^{Sc} or PrP-res).

The only organ system in which histopathological damage with its clinical effects is visible as a consequence of prion infection is the nervous system. This applies to all human TSEs and to all known prion encephalopathies of animals. However, it is apparent that prions can colonize organs other than the central and peripheral nervous system, and can be demonstrated in extracerebral compartments. A large body of incidental evidence has accumulated indicating that BSE prions can provoke new variant Creutzfeldt-Jakob disease (vCJD), although no ultimate proof has been presented—perhaps resulting from limitations of the analytical assays used for determining the characteristics of prions. Although most cases of human prion diseases are sporadic, about 10% run within family trees with a dominant pattern of transmission, and linked to one of a number of mutations in the gene encoding PrP. It is believed that these mutations allow spontaneous conversion of PrP^{C} into PrP^{Sc} with a frequency sufficient to cause disease within the lifetime of an individual.

HUMAN PRION DISEASES

Because the first description of CJD by Jakob and Creutzfeldt, five human diseases have been identified as TSEs (*see* Table 119-1). A striking hallmark applying to all TSEs is that the brain is heavily affected in sharp contrast to the extraneural tissues, which remain unharmed. To ultimately diagnose human prion diseases, a histopathological assessment of the CNS is essential. The communal lesions are neuronal loss, spongiosis, and astrogliosis, accompanied by an accumulation of microglia and, occasionally, the presence of amyloid plaques and various kinds of small deposits immunolabeled with anti-PrP antibodies (Fig. 119-1). These deposits are variable in their number and topography, hence representing one in a number of phenotypic variations typical of the various forms of human prion disease. The classifications of these disorders are being revised to incorporate genetic and biochemical data in addition to clinical and histopathological parameters.

CJD occurs sporadically with an incidence of approx 1–1.5 cases/million/yr, although higher incidence was reported in countries carrying out intensive surveillance programs. CJD may be transmitted through injection of infected tissues, and has a genetic basis in roughly 10% of all cases. Clinically, patients suffering from CJD show a wide spectrum of diversely associated symptoms. Besides the typical rapidly progressive form including dementia, myoclonia, cerebellar ataxia, visual disturbances, and periodic EEG

Table 119-1
Classification of Prion Diseases

Disease	*Host*	*Mechanism of pathogenesis*
Iatrogenic Creutzfeldt-Jakob disease	Humans	Infection from prion-contaminated pituitary hormones, dura mater grafts, and so on.
vCJD	Humans	Infection from BSE prions (hypothesized)
Familial CJD	Humans	Germ-line mutations in *PRNP* gene
sCJD	Humans	Unknown. Possibly somatic mutations resulting in spontaneous conversion of PrP^{C} into PrP^{Sc}?
Kuru	Fore people	Infection through ritualistic cannibalism
GSS disease	Humans	Germ-line mutations in *PRNP* gene
FFI	Humans	Germ-line mutations in *PRNP* gene
Fatal sporadic insomnia	Humans	Unknown
Scrapie	Sheep	Infection in genetically susceptible sheep
BSE	Cattle	Infection with prion-contaminated meat-and-bone meal
Transmissible mink encephalopathy	Mink	Infection with prions from sheep or cattle
Chronic wasting disease	Mule deer, white-tail deer, elk	Unknown
Feline spongiform encephalopathy	Cats	Infection with prion-contaminated bovine tissues or MBM
Exotic ungulate encephalopathy	Greater kudu, nyala, oryx	Infection with prion-contaminated MBM

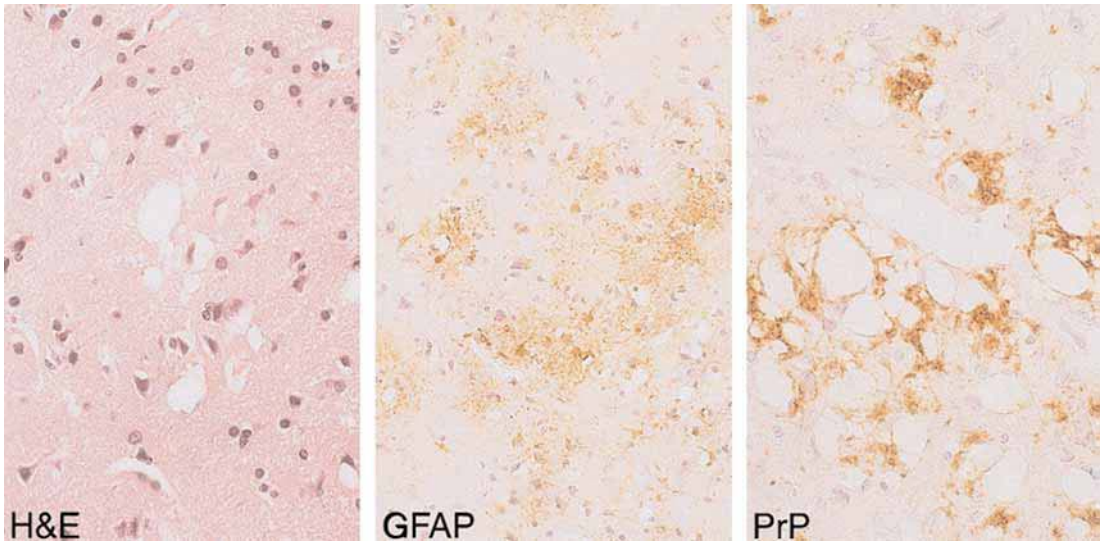

Figure 119-1 Characteristic neuropathologic features of transmissible spongiform encephalopathies. Grey matter of the brain of a Creutzfeldt-Jakob disease patient stained with hematoxylin-eosin (H&E) displaying the characteristic spongiform morphology (left). The normal texture is disturbed by the presence of coarse vacuoles. Antibodies against glial fibrillary acidic protein (GFAP; brown color, middle) allow for visualization of activated, proliferated reactive, swollen astrocytes. The immunohistochemical stain with anti-PrP antibodies evidences perivacuolar prion protein deposits (brown color, right). (Please *see* color insert.)

changes, other forms of the disease exist and may give rise to diagnostic difficulties. Albeit not completely diagnostic, periodic sharp wave complexes detected by EEG and 14-3-3 protein detection in spinal fluid are sometimes helpful for diagnosis, when clinical symptoms are present. There is no validated diagnostic procedure that would allow for confirmation of sporadic Creutzfeldt-Jakob disease (sCJD) in a patient short of brain biopsy, although it was reported that prions can be detected in the nasal mucosa of sCJD patients. Interestingly, there are no general symptoms such as fever or leukocytosis reminiscent of a humoral immune response.

The most recently recognized form of CJD in humans, vCJD, was first described in 1996 and has been linked to BSE. vCJD represents a distinct clinico-pathological entity characterized at onset by psychiatric abnormalities, sensory symptoms, and ataxia, eventually leading to dementia with other features usually observed in sCJD. What distinguishes vCJD from sporadic cases is that the age of patients is abnormally low (vCJD: 19–39 yr; sCJD: 55–70 yr) and duration of the illness is rather long (vCJD: 7.5–22 mo; sCJD: 2.5–6.5 mo). Moreover, the vCJD displays a distinct pathology within the brain characterized by abundant "florid plaques," decorated by a daisy-like pattern of vacuolation. Most cases of vCJD have been observed in the United Kingdom.

Other genetic diseases in humans are GSS syndrome and FFI. GSS is transmitted by autosomal-dominant inheritance. It is characterized by missense mutations of the gene encoding PrP (Fig. 119-2), associated with specific neuropathological lesions, and by multicentric amyloid plaques that can be visualized by antibodies directed against the prion protein. This restrictive definition justifies retaining the name of GSS syndrome and excludes observations of hereditary prion diseases without multicentric amyloid plaques, as well as sporadic forms with multicentric plaques. It has been possible to transmit GSS to chimpanzees

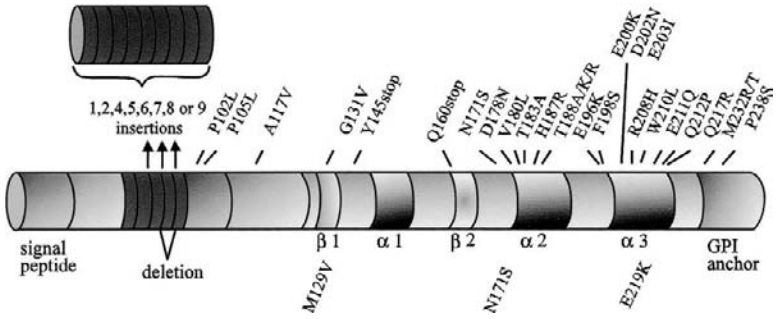

Figure 119-2 Schematic drawing of the coding region of the human PRNP gene. Mutations that segregate with inherited prion diseases are shown in the figure, as well as nonpathogenic polymorphisms and silent mutations. The N- and C-terminal domains are signal peptides that are cleaved off during maturation of PrP^{C}. Octa repeat regions are represented by dark gray boxes, and pathogenic octa repeat insertions of 16, 32, 40, 48, 56, 64, and 72 amino acids are shown in the figure. Deletion of one octa repeat stretch does not appear to segregate with a neurodegenerative disorder. The light gray box indicates a conserved region and β-sheet domains. There is an apparent clustering of pathogenic mutations associated with a Creutzfeldt-Jakob disease phenotype around the α-helical domains (H1, H2, H3, dark gray), whereas amino acid exchanges associated with a Gerstmann-Sträussler-Scheinker phenotype are located further upstream around the conserved region.

and to mice. An additional member of the group of TSEs, FFI, was also transmitted experimentally in at least three instances to mice. Kuru is a form of spongiform encephalopathies transmitted by ritual cannibalism, which affected the Fore population in the Northern provinces of New Guinea.

THE MOLECULAR BASIS OF BRAIN DAMAGE IN PRION DISEASES

Protease-resistant prion protein (PrP^{Sc}) deposits in the brain in most prion diseases. However, in some inherited cases PrP^{Sc} is hardly detectable, whereas ^{CTM}PrP, a transmembrane form of the prion protein, is abundant and may represent the prime pathogenetic moiety. This applies to a subset of people with GSS syndrome carrying a distinct mutation in the PrP gene, namely a substitution of alanine to valine at position 117 (*see* Fig. 119-2). Interestingly, this mutation, which leads to the irreversible neurodegeneration characteristic for prion diseases, is neither producing conventional PrP^{Sc} nor transmittable to laboratory rodents. It has been claimed that the effectiveness of accumulated PrP^{Sc} in causing neurodegenerative disease depends on the predilection of host-encoded PrP to be made in the ^{CTM}PrP form. In addition, the time course of PrP^{Sc} accumulation seems to modulate the events involved in generating ^{CTM}PrP suggesting a common mechanism in the pathogenesis of both genetic and acquired prion diseases—thus, possibly presenting not an exception but an explanation to the rule. This might explain why in many instances of human and experimental TSE extremely little PrP^{Sc} can be detected, even in terminal disease.

Cytosolic translocation of PrP^{C} has also been suggested to be involved in spongiform damage. A significant proportion of misfolded, secreted proteins can undergo retrotranslocation from the lumen of the endoplasmic reticulum to the cytosol, and targeting of a PrP^{C} variant to the neuronal cytosol was reported to be extremely neurotoxic in transgenic mice. It is conceivable that pathogenic missense mutations lead to enhanced production of misfolded prion protein and induce a late-onset metabolic disease by this mechanism. However, the exact biochemical pathways by which cytosolic PrP^{C} may arise are unclear and controversially debated.

THE BASIS OF PRION NEUROTROPISM

Although the prime target of damage seems to be neuronal, profound neuronal loss is not always seen in TSEs. Instead, activation of astrocytes, a brain-specific cell type, occurs early and in an extremely consistent fashion (*see* Fig. 119-1). It can be easily reproduced in vitro, and leads to significant physiological effects such as impairment of the blood–brain barrier. Additionally, astrocytes belong to the few cell types identified that are capable of supporting prion replication.

Growing evidence incriminates another cell type in brain damage, not only in TSEs but in diseases ranging from Alzheimer's to multiple sclerosis and even stroke: microglial cells, the brain's immunocompetent macrophages. In vitro experiments suggest that activation of microglia may be pivotal in effecting neuronal damage in TSEs, and that this phenomenon is dependent on expression of PrP^{C}; however, both claims have been subsequently challenged. The detailed pathways of neuronal cell death, therefore, still escape understanding. Future strategies to investigate the function of microglial cells in prion diseases may necessitate conditional lineage ablation strategies in trangenic mice.

HORIZONTAL TRANSMISSION OF PRIONS AMONG HUMANS

Prion diseases of humans are undeniably transmissible. But transmission is accomplished only under certain conditions, thus fulfilling the characteristics of transmissibility delineated by Semmelweiss for puerperal fever, prions are infectious but not contagious. Direct transmissions of brain-derived material from a patient suffering from CJD to other persons have proven to result in transmission of disease. A particularly tragic case occurred in the early seventies in Zurich, when electrodes used for cortical recordings from Creutzfeldt-Jakob patients were sterilized using formaldehyde vapors and alcohol, and used in additional patients. Disease was transmitted to two very young recipients. Moreover, several thousand patients, predominantly in Japan, may have been exposed to the CJD agent via preparations of prion-contaminated dura mater, although less than 2% of those exposed have developed disease so far. Also cornea transplantation likely resulted in transmission in the United States decades ago.

The largest problem with iatrogenic transmission of CJD has occurred as result of peripheral administration of pituitary hormones of cadaveric origin. Preparations of growth hormone and of gonadotropins contaminated with human prions have caused the death of more than 80 persons, of which most were children. Nonetheless, iatrogenic transmission is a rare event. This can be explained in two nonexclusive ways, either by the long incubation

time of prion diseases, especially in the earlier described case of extracerebrally administered growth hormones, assuming that further cases may arise within the future, or that some concomitant cofactors and endogenous modifiers, in addition to the virulence of prions, may affect the probability that infection takes place, thus either protecting or sensitizing individuals exposed to CJD prions.

The observations that latency after intracerebral contamination (such as cornea and dura mater transplants) is much shorter than latency after peripheral infection (as in the case of extracerebral application of pituitary hormones) is in agreement with experimental data from animal models, and suggest that a rather prolonged period of extracerebral events possibly including replication of the agent and invasion of specific extraneuronal systems may be a precondition to prion neuroinvasion.

NEUROINVASION–HOW PRIONS PAVE THEIR WAY TO THE CNS

Although prions are most effective when directly administered to the brain of their hosts, this situation occurs mainly in experimental lab work, and does not reflect the reality of the common routes of prion infections. Acquired forms of prion diseases are largely transmitted through oral uptake of the agent or peripheral administration—such as intramuscular injection of growth hormone and, to a lesser extent, pituitary gonadotropins—raising the question as to how prions find their way to the CNS.

Neuroectodermal tissue of *Prnp*$^{+/+}$ mice postnatally grafted into the brain of *Prnp*$^{o/o}$ mice develops into differentiated *Prnp*$^{+/+}$ nervous tissue. Intracerebral inoculation of such engrafted mice leads to typical scrapie pathology within the graft but not in the surrounding *Prnp*$^{o/o}$ tissue, whereas intraperitoneal infection does not, suggesting that prion transport from periphery to CNS requires interposed PrP-bearing tissue. Because no pathologies can be identified in organs other than the CNS it is of great importance to identify "reservoirs" within the periphery in which prions multiply (silently) during the incubation phase of the disease.

One such reservoir of PrP^{Sc} or infectivity is doubtlessly the immune system; studies point to the importance of prion replication in lymphoid organs. The nature of the cells supporting prion replication within the lymphoreticular system, however, is still uncertain. Inoculation of various genetically modified immunodeficient mice lacking different components of the immune system with scrapie prions revealed that the lack of B-cells renders mice unsusceptible to experimental scrapie. Whereas defects affecting only T lymphocytes had no apparent effect, all mutations affecting differentiation and responses of B-lymphocytes prevented development of clinical scrapie. Because absence of B-cells and of antibodies correlates with severe defects in follicular dendritic cells (FDCs), the lack of any of these three components may prevent clinical scrapie. FDCs have been incriminated, because PrP^{Sc} accumulates in FDCs of wild-type and nude mice (which suffer from a selective T-cell defect). Depletion of FDCs can block the replication of prions in the spleen.

Repopulation of immunodeficient mice with fetal liver cells from either PrP-expressing or PrP-deficient mice and from T-cell deficient mice, but not from B-cell deficient mice, is equally efficient in restoring neuroinvasion after intraperitoneal inoculation of scrapie prions. This suggests that cells whose maturation depends on B cells or their products (such as FDCs) may enhance neuroinvasion. Alternatively, B cells may transport prions to the nervous system by a PrP-independent mechanism, because PrP expression in B cells is not required for prion neuroinvasion. Interestingly, components of the complement system appear to play an important modulatory role in susceptibility to prion infection.

However, immune cells are unlikely to transport the agent all the way from the lymphoreticular system to the CNS, because prion replication occurs first in the CNS segments to which the sites of peripheral inoculation project. This implies that the agent may spread through other compartments, such as the peripheral nervous system (Fig. 119-3). There is experimental evidence implicating both the sympathetic and the parasympathetic nervous systems.

APPROACHES TO THE THERAPY OF PRION DISEASES

Despite that no patient and no experimental animal were ever rescued from manifest prion disease, developments appear to suggest that immunological and pharmacological interventions may bear some potential for pre-exposure and postexposure prophylaxis. Although no realistic prospect for curing the clinically overt stages of prion diseases exists, an increasing arsenal of palliative and even life-prolonging interventions is being tested in experimental and clinical settings.

Preincubation with anti-PrP antisera reduces the prion titer of infectious hamster brain homogenates and anti-PrP antibodies inhibit formation of PrP^{Sc} in a cell-free system. Also, antibodies and F(ab) fragments raised against certain domains of PrP can suppress prion replication in cultured cells. However, it is difficult to induce humoral immune responses against PrP^{C} and PrP^{Sc} because of tolerance to PrP^{C}, which is expressed almost ubiquitously. Ablation of the *Prnp* gene, which encodes PrP^{C}, renders mice highly susceptible to immunization with prions. However, *Prnp*$^{o/o}$ mice are unsuitable for testing vaccination regimens because they do not support prion pathogenesis.

Introduction of the epitope-interacting region, the heavy chain of a high-affinity anti-PrP monoclonal antibody, into the germ line of mice induced spontaneous anti-PrP^{C} immunity. Most intriguingly, expression of the 6H4μ heavy chain blocked peripheral prion pathogenesis on intraperitoneal inoculation of the prion agent. This delivers proof-of-principle that a protective humoral response against prions can be mounted by the mammalian immune system, and suggests that B cells are not intrinsically tolerant to PrP^{C}. These data were confirmed by passive transfer of immunoglobulins.

If the antiprion effect of anti-PrP^{C} antibodies is generally true, lack of immunity to prions may be resulting from T-helper tolerance. The latter problem is not trivial, but may perhaps be overcome by presenting PrP^{C} to the immune system along with highly active adjuvants. These findings, therefore, encourage a reassessment of the possible value of active and passive immunization, and perhaps of reprogramming B-cell repertoires by μ chain transfer, in prophylaxis or in therapy of prion diseases.

The possibility of producing protective immunity against prions has, in the meantime, captured the imagination of a considerable number of scientists, and additional reports are appearing of original ways to break tolerance and induce an immune response in animals that express the normal prion protein, including passive immunization and mixing of the immunogenic moiety with bacterial chaperons.

It was claimed that chronic administration of CpG-containing oligodeoxynucleotides, which stimulate the innate immunity receptor TLR9, can accomplish postexposure prophylaxis against prion diseases. Details of this surprising phenomenon show that

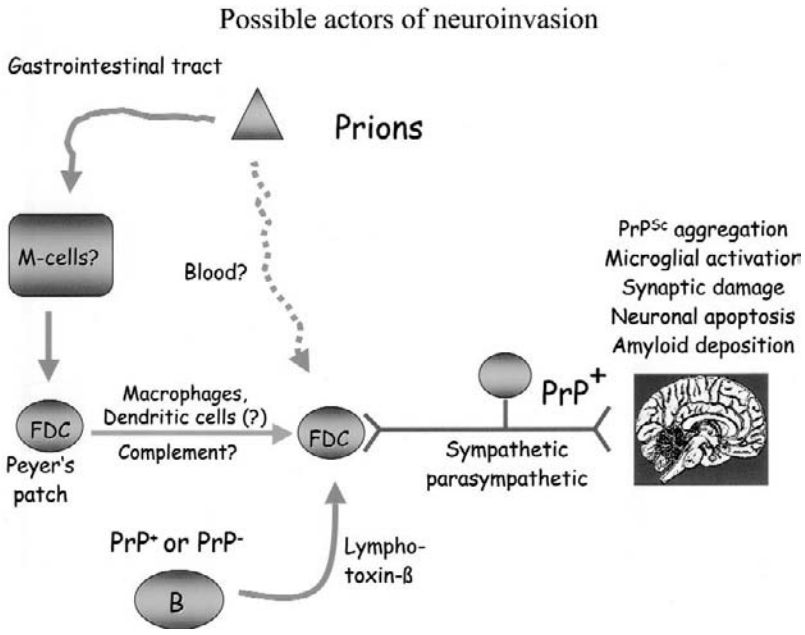

Figure 119-3 Possible models for prion neuroinvasion. In the upper panel, B lymphocytes, which may be genotypically PrP-positive or PrP-negative, physically carry prions to their sites of replication in spleen. These may be represented, in part or entirely, by FDCs. Neuroinvasion proper then occurs preferentially along fibers of the peripheral nervous system, which may support transfer of prions to the CNS depending on their own expression of PrP^C. The lower panel illustrates a second possibility, i.e., that B cells are not directly involved in neuroinvasion. In this instance, the crucial role of B-cells in neuroinvasive scrapie relies on their function in inducing maturation of FDCs.

this treatment abolishes germinal center networks and ablates FDCs, which are the major reservoir of prion infectivity in the periphery. CpG oligodeoxynucleotide protect against prions by virtue of their toxic side effects, and therefore are hardly suitable for clinical applications in this context.

MOLECULAR BIOLOGY OF PRIONS

PrP^C has been identified in all mammals and birds examined, and it is anchored to the external surface of cells by a glycolipid moiety. Its function is unknown. Attempts to identify a post-translational chemical modification that distinguishes PrP^{Sc} from PrP^C have been unsuccessful. PrP^C contains approx 45% α-helix and is virtually devoid of β-sheet. Conversion to PrP^{Sc} creates a protein that contains approx 30% α-helix and 45% β-sheet. The mechanism by which PrP^C is converted into PrP^{Sc} remains unknown but PrP^C seems to bind to PrP^{Sc} and to form an intermediate complex during the formation of nascent PrP^{Sc}. Transgenic mouse studies have demonstrated that PrP^{Sc} in the inoculum interacts preferentially with homotypic PrP^C during the propagation of prions.

Prnp is transcribed in brain and many other cells of the body in both prion-infected and noninfected animals. Removal of *Prnp* from the mouse genome leads to complete immunity from prions. The emergence of a vCJD in young people in the UK has raised the possibility that BSE has spread to humans by dietary exposure. Experimental evidence claiming that the agent causing BSE is indistinguishable from the vCJD agent has supported this view.

THE CONVERSION OF PRP^C INTO PRP^{SC}

Accumulation of an abnormal isoform (PrP^{Sc}) of the host encoded PrP^C in the CNS is a hallmark of prion diseases. Because no chemical differences were found between PrP^C and PrP^{Sc}, the two species are believed to differ in their conformation. The fine 3D structure of PrP^C has been resolved at the atomic level using both nuclear magnetic resonance spectroscopy and X-ray diffraction crystallography. Instead, only low-resolution structural data exist for PrP^{Sc}, which have been extended to electron crystallography. The β-sheet content of PrP^{Sc} was found to be high, whereas PrP^C contains only a very short β-sheet stretch. Conversion of PrP^C into PrP^{Sc} in prion-infected cells is known to be a late post-translational process, occurring after PrP^C has reached its normal extracellular location.

To explain the mechanism by which a misfolded form of PrP might induce the refolding of "native," normal PrP molecules into the abnormal conformation, two distinct models have been postulated: the template assistance or "refolding" model, and the nucleation-polymerization or "seeding" model (Fig. 119-4). In the first model, the conformational change is kinetically controlled; a high activation energy barrier prevents spontaneous conversion at detectable rates. Interaction with exogenously introduced PrP^{Sc} causes PrP^C to undergo an induced conformational change to yield PrP^{Sc}. This reaction may involve extensive unfolding and refolding of the protein to explain the postulated high energy barrier and could be dependent on an enzyme or chaperone, provisionally designated as protein X. In the second model, PrP^C and PrP^{Sc} are in equilibrium strongly favoring PrP^C. PrP^{Sc} is only stabilized when it adds onto a crystal-like aggregate of PrP^{Sc} acting as a seed in a nucleation-dependent polymerization process. Cell-free conversion studies suggest that PrP^{Sc} aggregates are able to convert PrP^C into a protease-resistant PrP isoform.

THE PRION PROTEIN

The cellular prion protein PrP^C contains two N-linked complex-type oligosaccharides at positions 181 and 197. Accordingly, Western blot analysis of PrP reveals three major bands, reflecting PrP that has two, one, or no glycosylation signals occupied. On translocation of PrP into the endoplasmic reticulum, an NH_2-terminal secretory

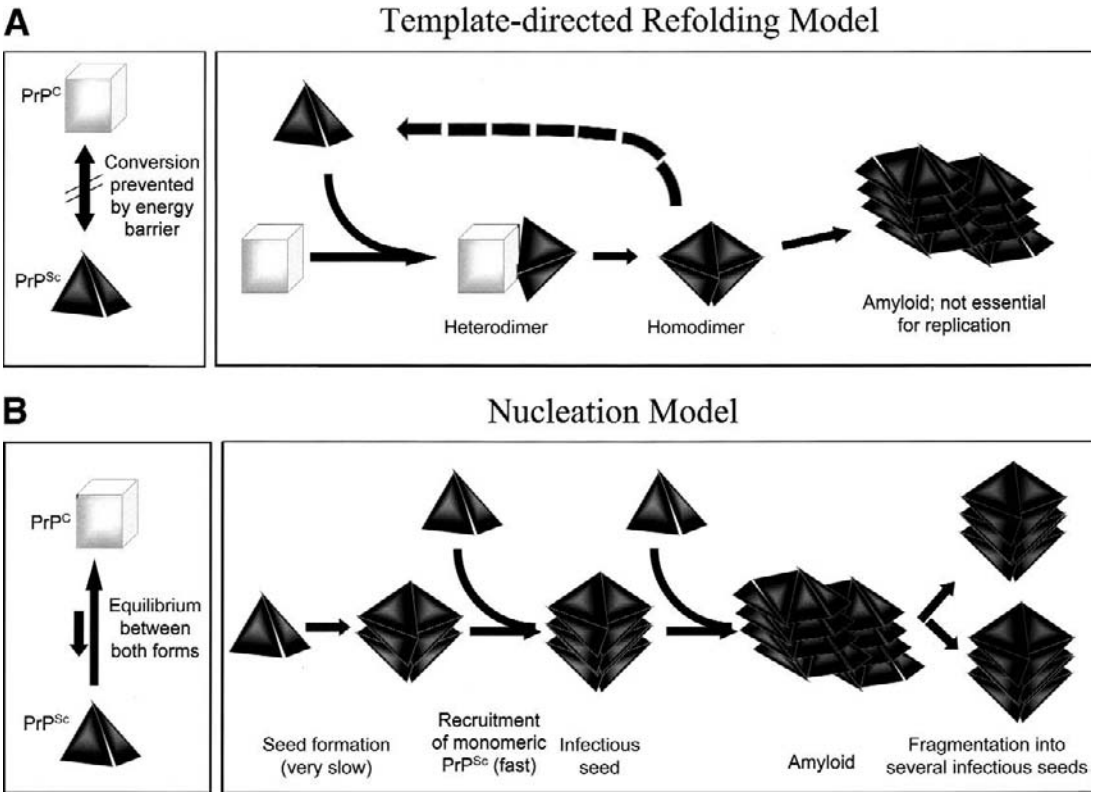

Figure 119-4 Models for the conformational conversion of PrP^{C} into PrP^{Sc}. **(A)** The "refolding" or template assistance model postulates an interaction between exogenously introduced PrP^{Sc} and endogenous PrP^{C}, which is induced to transform itself into further PrP^{Sc}. A high energy barrier may prevent spontaneous conversion of PrP^{C} into PrP^{Sc}. **(B)** The "seeding" or nucleation-polymerization model proposes that PrP^{C} and PrP^{Sc} are in a reversible thermodynamic equilibrium. Only if several monomeric PrP^{Sc} molecules are mounted into a highly ordered seed, further monomeric PrP^{Sc} can be recruited and eventually aggregates to amyloid. Within such a crystal-like seed, PrP^{Sc} becomes stabilized. Fragmentation of PrP^{Sc} aggregates increases the number of nuclei, which can recruit further PrP^{Sc} and thus results in apparent replication of the agent.

signal peptide of 22 amino acids is cleaved from PrP, and twenty-three COOH-terminal residues are processed during addition of the GPI-anchor to the amino acid residue serine at position 231. Mature mouse PrP contains 209 amino acids.

PrP^{Sc}, which accumulates in TSE-affected organisms is a modified form of PrP^{C}. PrP^{C} and PrP^{Sc} have an identical amino acid sequence and share the same posttranslational modifications as assessed by available methodology, but differ in their secondary and (presumably) tertiary structure. The physiological isoform PrP^{C} is protease-sensitive (consequently sometimes designated as PrP^{sen}), whereas the pathological isoform PrP^{Sc} is partially protease-resistant (thus also called PrP^{res}). The protease-resistant core of PrP^{Sc}, designated $PrP^{27–30}$ according to its molecular weight on SDS-PAGE, provides a specific and reliable molecular marker for the presence of the infectious agent (Fig. 119-5).

Because of its location at the outer surface of cells, anchored by phosphatidyl inositol glycolipid, PrP is a candidate for signaling, cell adhesion, or perhaps even for some transport functions. PrP is expressed on many cell types, including neurons, glial cells, and lymphocytes and appears to be developmentally regulated during mouse embryogenesis. All prion proteins investigated contain 4-5 "octa repeats," repetitive sequences of eight amino acids. Amplification of the number of octa repeats has been found in hereditary prion diseases such as Familial CJD and GSS syndrome. Several studies have established that mammalian and chicken prion protein octa repeats bind up to four copper atoms. It has been suggested from studies with peptides based on the octa repeat region of PrP that the four highly conserved histidines in the repeat region coordinate four copper atoms suggest that binding of copper may be essential for the function of PrP^{C}. PrP refolded with copper has been purported to have an antioxidant activity similar to superoxide dismutase, but these claims were not independently reproduced and there is no evidence that PrP^{C} acts as a superoxide dismutase in vivo.

Although PrP is predominantly found in brain tissue, high levels are also present in heart, skeletal muscle and kidney whereas it is barely detectable in the liver. Several candidate proteins that bind PrP^{C} have been reported. Among them are a member of the amyloid precursor protein, the amyloid precursor-like protein 1 (APLP1), the antiapoptotic protein bcl-2, and the 37 kDa human laminin receptor precursor. The observation that PrP binds to APLP1 is intriguing in light of potential analogies of TSEs to Alzheimer's disease. Evidence that any of these interactions are of physiological relevance is, however, still amiss.

PRNP—THE GENE ENCODING PRP

The gene encoding the cellular isoform of the prion protein is located on chromosome 20 in humans and on chromosome 2 in mice, and is termed *Prnp* in mouse and *PRNP* in humans. In all known mammalian and avian *Prnp* genes, PrP^{C} is encoded by a single open reading frame. The *Prnp* genes of mouse, sheep, and cattle contain 3 exons, although those of hamsters and humans span over 2 exons. PrP expression seems to be controlled by the SP1 transcription factor that binds to G+C rich nonamer-regions

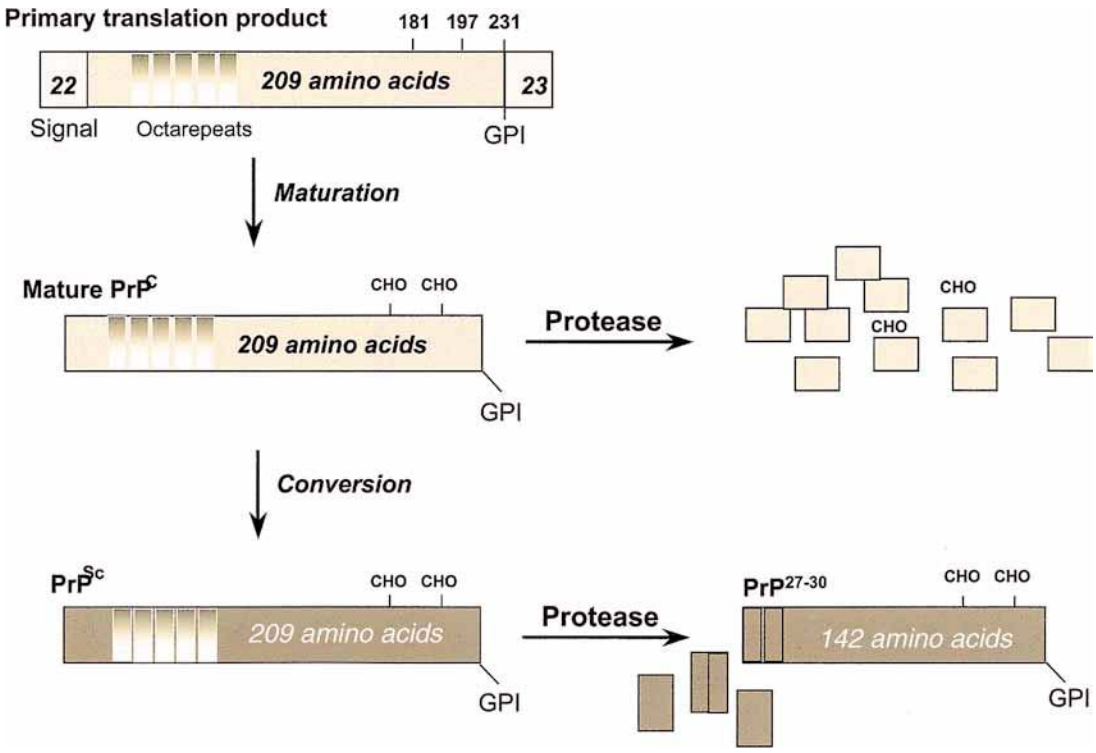

Figure 119-5 Post-translational processing of PrP^C. The coding region of the human PrP gene displaying the amino- and carboxy-terminal signal sequences; the five internally shaded boxes indicate the "octa repeats," sequences of eight amino acids. On reaching its destination on the cell surface, an amino-terminal secretory signal peptide of 22 amino acids is cleaved from the 254 amino acid PrP^C precursor protein. Twenty-three carboxy-terminal residues are also processed during addition of the GPI-anchor to a serine residue at position 231. On completion of these modifications, mature PrP^C contains 209 amino acids. PrP^{Sc} is a modified form of PrP^C. PrP^C and PrP^{Sc} have an identical amino acid sequence and share the same post-translational modifications, but differ in their secondary and (presumably) tertiary structure. The physiologic isoform PrP^C is protease-sensitive, whereas the pathological isoform PrP^{Sc} is partially protease-resistant displaying a protease-resistant core of PrP^{Sc}, designated PrP 27-30.

upstream of exon 1. Within the genome, *Prnp* is present as a single copy gene. A partial homologue gene termed *Prnd*, and encoding the *Dpl* protein ("downstream of the *Prnp* locus"), was identified approx 16 kb 3′ from the *Prnp* locus. No evidence incriminates *Dpl* in the pathogenesis of transmissible prion diseases, and the physiological function of *Dpl* seems to be related to male reproduction.

Prnp mRNA is constitutively expressed in the adult organism and developmentally regulated during mouse embryogenesis. Mutations in the host-encoded PrP gene are genetically linked to human prion diseases. In addition, polymorphisms in the PrP gene control many features of prion diseases including incubation time, species barrier, and specificity of recovered prion strain. Mice that lack PrP^C (denominated $Prnp^{o/o}$ or $Prnp^{-/-}$) are resistant to infection with prions.

Interestingly, $Prnp^{o/o}$ mice of an amino proximally truncated transgene encoding PrP devoid of the octa repeats and the conserved 106-126 region suffer from ataxia and degeneration of the cerebellar granule cells shortly after birth. Similar (but not identical) phenotypes are observed in mice overexpressing Dpl, which experience degeneration of cerebellar Purkinje cells. Introduction of a single intact PrP allele largely rescues this phenotype. These findings may be explained by postulating that PrP interacts with a ligand to obtain an essential signal. In the absence of PrP, a notional PrP-like molecule with lower binding affinity may arguably supply the missing PrP function. According to this hypothesis, in PrP knockout mice by interacting with the ligand the truncated PrP could displace the PrP-like molecule without eliciting a survival signal. In case PrP has the highest affinity for the ligand, it would replace its truncated equivalent and restore function.

An alternative explanation posits that Dpl or amino-terminally truncated PrP^C can exist as transmembrane proteins and form oligomers. Lack of the amino terminus may create a toxic channel that would be patent for ions and lead to osmotic or excitotoxic damage. Single molecules of PrP^C containing its amino-terminal tail may block such channels in a transdominant fashion, and thereby abrogate neurotoxicity.

THE SPECIES BARRIER

Transmission of prions from one species to another is usually accompanied by a prolongation of the incubation period in the first passage and incomplete penetrance ("attack rate") of the disease. This phenomenon is called the "species barrier." Subsequent passage in the same species occurs with high frequency and shortened incubation times. In the case of prion transmission from hamster to mice, this species barrier was overcome by introducing hamster *Prnp* transgenes into recipient wild-type mice. Crucially, the properties of the prions produced were compatible with the prion species used for inoculation; infection with hamster prions led to production of hamster prions, whereas infection with mouse prions gave rise to mouse prions. With respect to the protein-only hypothesis these findings can be interpreted as follows: hamster PrP^C but not murine PrP^C (the latter differing from the former by 10 amino acids) is an appropriate substrate for conversion to hamster PrP^{Sc} by hamster prions and vice versa. Intriguingly, susceptibility of mice to prions

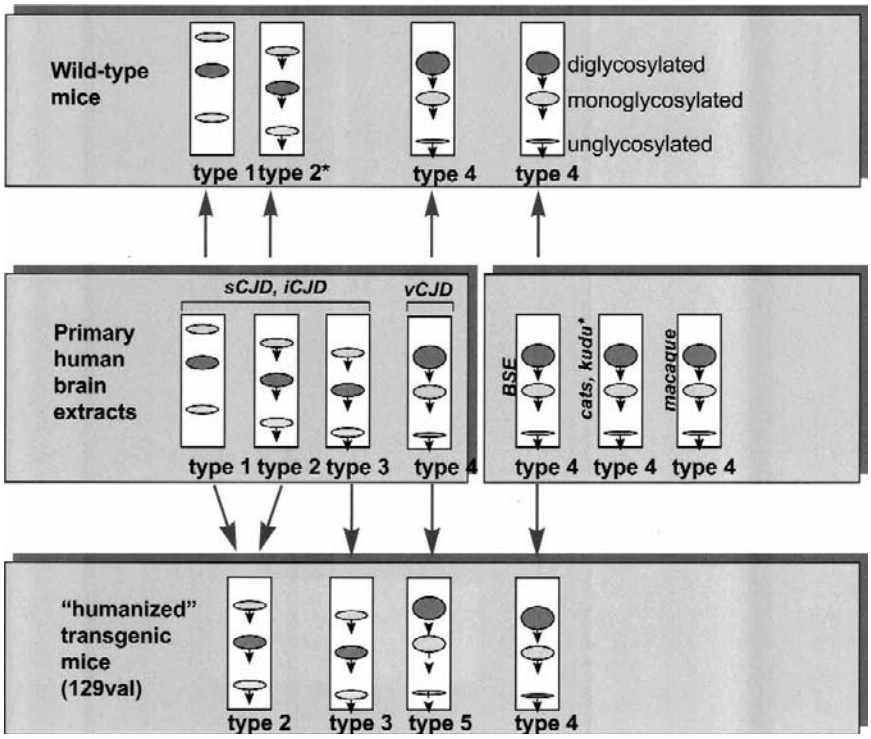

Figure 119-6 Patterns of PrP glycosylation. Representation of the three glycosylated PrP^{Sc} moieties (non-, mono-, and diglycosylated PrP^{Sc}) in immunoblots of brain extracts after digestion with proteinase K. Different inocula result in specific mobilities of the three PrP bands as well as different predominance of certain bands (middle panel). These characteristic patterns can be retained, or changed to other predictable patterns after passage in wild-type (upper panel) or humanized mice (PrP-deficient mice bearing a human PrP transgene, lower panel). Based on the fragment size and the relative abundance of individual bands, three distinct patterns (PrP^{Sc} types 1–3) were defined for sporadic and iatrogenic Creutzfeldt-Jakob disease cases. In contrast, all cases of variant Creutzfeldt-Jakob disease displayed a novel pattern, designated as type-4 pattern.

from other species is increased when the corresponding PrP transgene is introduced into a PrP knockout mouse, suggesting that the resident murine gene inhibits the propagation of the alien prions.

UNDERSTANDING PRION STRAINS

In 1961, distinct isolates or strains of prions were first described in scrapie-diseased goats, in which two dissimilar clinical manifestations ("scratching" and "drowsy," respectively) were identified. These strains differ in their incubation times in various inbred mouse lines and by their lesion pattern in the brain. Strikingly, distinct strains of prions can be propagated in an inbred mouse strain that is homozygous with respect to *Prnp*, a perplexing finding regarding the protein-only hypothesis, meaning that an identical polypeptide chain is able to mediate different strain phenotypes. Both the "refolding" and the "seeding" model propose that each strain is associated with a distinct conformation of PrP^{Sc} and that each of these can convert PrP^{C} of its host into a likeness of itself. Indeed, PrP^{Sc} species associated with two hamster-adapted scrapie strains, hyper and drowsy, proved to display characteristic clinical and histopathological properties as well as distinct biochemical patterns with respect to proteinase K digestion, which may be explainable by the presence of different conformations of PrP^{Sc}. Analogous findings have been made with other prion strains propagated in mice. In addition, PrP^{Sc} of certain strains differ in the ratio of diglycosylated to the monoglycosylated form. Based on the fragment size and the relative abundance of individual bands, three distinct patterns (PrP^{Sc} types 1–3) were defined for sporadic and iatrogenic CJD cases. In contrast, all cases of vCJD displayed a novel pattern, designated type-4 by Collinge, and type III by Parchi and Gambetti (Fig. 119-6). Interestingly, brain extracts from BSE-infected cattle and BSE-inoculated macaques exhibited a type-4 pattern. Even more intriguingly, transmission of BSE or vCJD to mice produced mouse PrP^{Sc} with a type-4 pattern indistinguishable from the original inoculum–findings that impressively support the hypothesis that vCJD is the human counterpart to BSE. An additional tool, which may eventually serve to characterize prion strains, utilizes the differential affinity of certain antibodies for properly folded and denatured isoforms of PrP, thereby differentiating as many as eight different conformers. This provides further circumstantial evidence for the assumption that strain specificity is encrypted within the physical structure of PrP.

Studies of scrapie in inbred mice led to identification of a single autosomal gene, termed *Sinc* (*scrapie incubation*), controlling incubation time of mice infected with mouse prion strains. Soon after, a link between *Sinc* and a polymorphism in the mouse *Prnp* gene was discovered. Elegant knock-in experiments, in which *Prnp* alleles of inbred mice were swapped, have provided strong support for the contention that *Sinc* is identical to *Prnp*.

YEAST PRIONS

For more than 20 yr the genetic analysis of two unrelated mutants of the fission yeast *Saccharomyces cerevisiae* caused a substantial dilemma to yeast researchers. The two mutants in

question, the [*PSI*$^{+}$] mutant (modifying the efficiency of nonsense suppression) and the [*URE3*] mutant (causing an alteration in nitrogen metabolism) failed to behave according to Mendel's laws. The unusual genetic properties of both mutants were explained by a prion-like behavior of two previously identified yeast proteins: [*PSI*$^{+}$] is associated with Sup35p (also known as eRF3), an essential component of the translation termination machinery, whereas [*URE3*] is associated with Ure2p, a protein that negatively regulates nitrogen metabolism. Further yeast proteins with a prion-like behavior have been discovered; among them is Rnq1p fulfilling all diagnostic criteria of yeast prions, although obviously not associated with a specific phenotype.

Strikingly, the prion-forming domain (PrD) of Sup35p is both modular and transferable. An artificial prion was generated by fusing a recombinant version of a mammalian receptor to the Sup35p-PrD. The fusion protein altered the biochemical properties of yeast cells in ways that could be inherited by progeny cells. The modular and transferable properties of yeast PrD provide strong support for the "yeast protein only" hypothesis, and may have considerable evolutionary and biotechnological implications, if broadly applicable.

In a further set of experiments, both yeast and a neural tumor cell line cytoplasmically expressing mouse PrP acquired the characteristics of PrP^{Sc}, detergent insolubility and resistance to protease digestion. Cytosolic PrP was shown to be selfsustaining (however, only within one single cell, and not from one individual to another, which is what would be expected from real prions) and highly neurotoxic when expressed in transgenic mice.

Overall, yeast is providing a powerful and experimentally testable paradigm for prions, although caution must be taken in directly extrapolating from findings with yeast prions to the mammalian system.

120 Narcolepsy and Other Neurological Sleep Disorders

THOMAS E. SCAMMELL

SUMMARY

Sleep disorders are among the most common clinical ailments, and molecular research is beginning to shed light on the neurobiology of sleep and the mechanisms underlying specific disorders of sleep. This chapter focuses on sleep disorders with a neurological basis, particularly those in which recent discoveries have realed the underlying molecular biology.

Key Words: Arousal; circadian rhythms; hypocretin; insomnia; narcolepsy; orexin; REM behavior disorder; sleep; sleep disorders; suprachiasmatic nucleus; wakefulness.

NEUROBIOLOGICAL CONTROL OF SLEEP AND WAKEFULNESS

Sleep consists of two major states: rapid eye movement (REM) sleep and nonrapid eye movement (NREM) sleep. REM sleep is characterized by cortical activation with vivid dreams, brief saccadic eye movements, and intense paralysis of most voluntary muscles. In NREM sleep, cortical activity and mentation are minimal, and autonomic activity is low.

To understand the basis of many sleep disorders, it is helpful to review some of the pathways involved in the control of behavioral state. Normal wakefulness requires the coordinated activity of several ascending arousal systems located in the rostral brainstem and posterior hypothalamus (Fig. 120-1). Cholinergic innervation of the thalamus from the pedunculopontine tegmental and laterodorsal tegmental nuclei (PPT/LDT) facilitates thalamocortical signaling and activates the cortex during wakefulness. During NREM sleep, these cholinergic neurons are much less active, thus decreasing thalamic and cortical activity. A separate population of cholinergic neurons in the basal forebrain helps to generate full attention and cortical functioning, but it is unclear whether these cells are required for the production of wakefulness itself.

Monoaminergic neurons also are essential for the production of wakefulness. The noradrenergic neurons of the locus ceruleus (LC), serotonergic neurons of the dorsal raphe (DR) nuclei, and histaminergic neurons of the tuberomammillary nucleus (TMN) diffusely innervate and activate much of the forebrain, firing most rapidly during wakefulness, slower in NREM sleep, and then becoming silent in REM sleep. The role of dopaminergic neurons is less clear, but one cell group in the ventral periaqueductal gray is active during wakefulness and may be a critical site for dopaminergic effects on wakefulness.

These cholinergic and monoaminergic regions interact to produce REM sleep. A distinct population of REM-on cholinergic neurons in the PPT/LDT activates the thalamus during REM sleep, producing cortical activation and atonia through descending spinal projections. The LC, DR, and TMN inhibit the REM sleep-producing neurons during wakefulness and NREM sleep, but during REM sleep, these monoaminergic nuclei become inactive, thus disinhibiting the REM-generating neurons.

NREM sleep is produced by neurons in the preoptic area and brainstem. The dorsal vagal complex, raphe nuclei, and ventral midbrain contain some NREM-generating cells, but the ventrolateral preoptic area (VLPO) is the best characterized sleep-producing region. VLPO neurons are active during NREM and REM sleep and are necessary for sleep because lesions of the VLPO produce marked insomnia. These γ-aminobutyric acid-containing neurons help maintain sleep by inhibiting neurons in the TMN, LC, and DR. In turn, VLPO neurons are inhibited by monoamines during wakefulness, thus creating a reciprocally inhibitory circuit in which wake- and sleep-promoting regions inhibit one another.

Two major factors influence the timing of sleep and wakefulness. Homeostatic sleep drive increases with prolonged wakefulness, and rising levels of sleep-promoting factors such as adenosine and prostaglandin D2 provide part of this drive. When cats are kept awake for several hours, the concentration of the neuromodulator adenosine rises in the basal forebrain. This adenosine disinhibits the sleep-producing neurons of the VLPO, thus, promoting sleep. Caffeine probably promotes wakefulness by blocking this adenosine signaling. The timing of sleep and wakefulness is also strongly influenced by circadian rhythms.

CIRCADIAN RHYTHMS

Nearly all living organisms organize their physiology and behavior around the daily cycle of light and darkness. However, these circadian rhythms are not simply driven by the ambient light cycle; they are endogenously generated rhythms that persist in constant darkness. In mammals, circadian rhythms are controlled by the suprachiasmatic nucleus (SCN), a small cluster of neurons just above the optic chiasm in the anterior hypothalamus. The SCN acts as a master clock, keeping time with an accuracy of a few

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

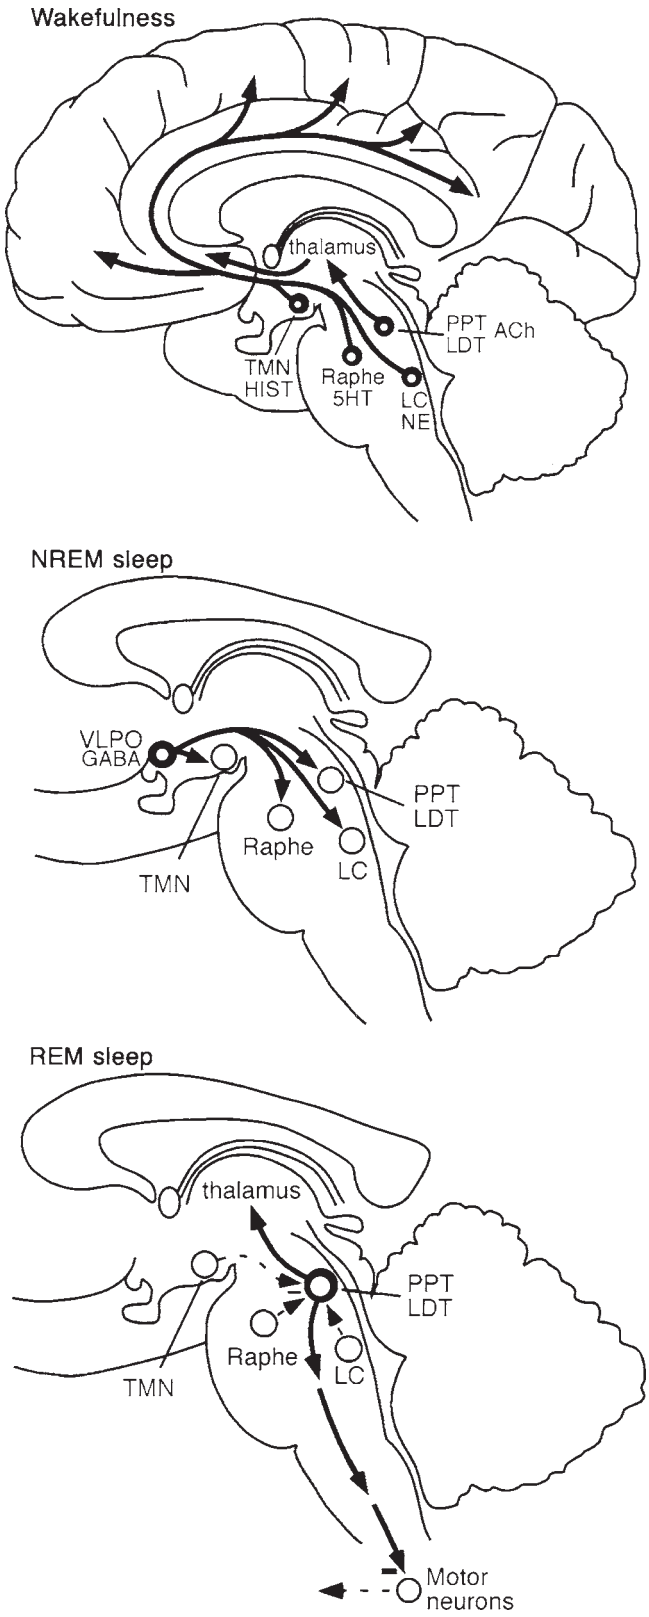

Figure 120-1 Pathways for the production of wakefulness, NREM sleep, and REM sleep. During wakefulness, the forebrain is widely activated by projections from aminergic nuclei including the noradrenergic LC, serotonergic (5HT) raphe nuclei, and histaminergic (HIST) tuberomammillary nucleus. Cholinergic (ACh) fibers from the PPT/LDT innervate the thalamus to promote thalamocortical signaling. During NREM sleep, γ-aminobutyric acid (GABA)-containing neurons of the VLPO inhibit these aminergic and cholinergic regions to promote sleep. In REM sleep, a specific set of cholinergic neurons in the PPT/LDT activates the thalamus and also inhibits motor neurons through a series of descending projections. These REM-active PPT/LDT neurons are inhibited by aminergic brain regions during wakefulness. Nuclei with thick outlines are active during each state.

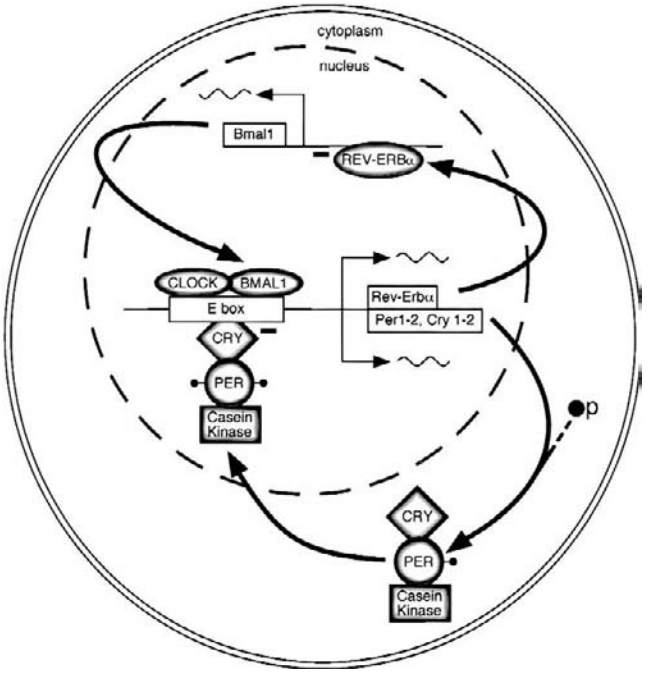

Figure 120-2 Molecular mechanism of circadian rhythmicity in SCN neurons. CLOCK and BMAL1 act on an E box enhancer to increase the expression of *per* and *cry* mRNAs. In the cytoplasm, PER forms a complex with CRY and is phosphorylated by casein kinase. This complex moves back into the nucleus and inhibits expression of the *per* and *cry* genes, thus forming a negative feedback loop. REV-ERBα inhibits the expression of *Bmal1*, but the PER/CRY complex also decreases expression of *Rev-Erbα*, thus, allowing production of BMAL1. These positive and negative feedback loops most likely generate daily rhythms in SCN neurons.

minutes each day, and adjusting bodily rhythms to seasonal variations in day length. Most likely, each SCN neuron is a competent circadian pacemaker, and the coordinated activity of all SCN neurons results in highly accurate 24-h rhythms. The importance of this nucleus is apparent in people and animals with lesions of the SCN who may sleep and wake at any time of day.

MOLECULAR BIOLOGY OF CIRCADIAN RHYTHMS

Molecular biological studies have identified the fundamental mechanisms that generate daily rhythms in SCN neurons. The core mechanism involves daily cycles of gene expression that are driven by autoregulatory feedback loops in which clock gene products regulate the expression of their own mRNA (Fig. 120-2).

Two transcription factors, CLOCK and BMAL1, provide the basic drive to these rhythms. CLOCK/BMAL1 heterodimers constitutively bind to E box enhancers to increase the production of *period* (*Per1*, *Per2*, and *Per3*) and *cryptochrome* (*Cry1* and *Cry2*) transcripts. The PER and CRY proteins form a complex that inhibits expression of the *per* and *cry* genes by interfering with the enhancing effects of CLOCK and BMAL1. Thus, rising levels of PER eventually shut down the expression of *per* and *cry*, and PER and CRY protein levels fall. Phosphorylation of the PER/CRY

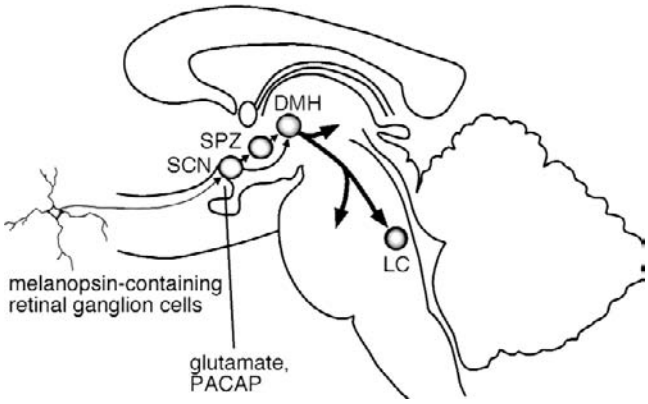

Figure 120-3 Pathways that govern circadian rhythms. The SCN is the master regulator of circadian rhythms. The phase of SCN activity is adjusted to the ambient light–dark cycle by luminance information from melanopsin-containing retinal ganglion cells. The SCN sends timing signals to the SPZ and DMH. The DMH then relays these signals to the LC and other state-regulatory brain regions. PACAP, pituitary adenylate cyclase activating peptide.

complex by casein kinase (CKIε and CKIδ) hastens the degradation of PER, thereby slowing the rate of this negative feedback loop.

A positive feedback loop occurs when CLOCK and BMAL1 increase the transcription of a nuclear receptor, REV-ERBα. REV-ERBα inhibits the transcription of *Bmal1*. However, the PER/CRY complex inhibits expression of *Rev-Erbα*, thus disinhibiting BMAL1 production. This positive (double negative) feedback loop allows *Bmal1* mRNA levels to peak 12 h out of phase with those of the *per* and *cry* genes.

The functional importance of these genes has been demonstrated in several lines of knockout mice. In the absence of environmental time cues, mice lacking both *per1* and *per2* or both *cry* genes cannot generate circadian rhythms. Similar behavior is seen in mice lacking the genes for *Bmal1* or *clock*. In hamsters, a mutation in the gene for *casein kinase Iε* results in very short rhythms, probably because poorly phosphorylated PER and CRY degrade more slowly, accumulate rapidly, and, thus, inhibit their own expression more quickly.

MELANOPSIN AND THE RETINOHYPOTHALAMIC TRACT The SCN receives photic information directly from the retina, and these signals help synchronize SCN neuronal activity with the ambient light–dark cycle (Fig. 120-3). Unlike the more familiar pathways that mediate visual perception, the retinohypothalamic tract carries luminance information from the retina to the SCN and other diencephalic and midbrain regions. These fibers release glutamate and pituitary adenylate cyclase-activating peptide onto SCN neurons which markedly increases the expression of PER, shifting the phase of the molecular clock.

Surprisingly, this photoentrainment does not require rods and cones, but studies have identified a novel photopigment known as melanopsin that helps generate this luminance signal. In contrast to the classic photopigments found in rods and cones, melanopsin is produced in a small subset of retinal ganglion cells with large dendritic fields. These ganglion cells project directly to the SCN, and in isolated retinal preparations, the firing rate of these neurons increases in response to light, even when synaptic transmission has been blocked. Thus, these inherently photoreceptive ganglion cells are well positioned to transmit luminance information to the SCN. The functional importance of this system has been demonstrated in mice lacking melanopsin. In response to a 15-min pulse of light, these mice have much smaller shifts in their circadian rhythms than normal mice. Because some shifts still occur, rods, cones, and the melanopsin system probably work together to entrain circadian rhythms.

PATHWAYS THROUGH WHICH THE SCN MAY CONTROL BEHAVIORAL STATE The SCN drives circadian rhythms through synaptic and humoral processes. The SCN heavily innervates several hypothalamic regions, especially an area just dorsal to the SCN known as the subparaventricular zone (SPZ). Lesions of the SPZ block circadian rhythms of sleep/wake behavior and body temperature. The SPZ projects to the dorsomedial nucleus of the hypothalamus (DMH), and DMH lesions also block sleep/wake rhythms. The DMH then relays these timing signals to wake-promoting regions such the orexin neurons and LC, which help promote wakefulness and suppress REM sleep during the day.

Humoral factors secreted from the SCN also influence the timing of sleep. SCN-lesioned animals lack circadian rhythms, but rhythms can be restored with SCN transplants. This restoration of rhythmicity does not require synaptic connections because the daily rhythm of locomotor activity can be partially restored with SCN transplants encased in a polymer that blocks the outgrowth of neurites but allows passage of small molecules. These secreted timing factors include transforming growth factor (TGF)-α and prokineticin 2 (PK2). In nocturnal rodents, TGF-α and PK2 expression is high during the day, and infusion of these peptides suppresses locomotor activity. TGF-α and PK2 receptors are expressed in targets of the SCN, including the SPZ and DMH. Chronic infusions of TGF-α block the circadian variation in sleep/wake behavior in a pattern similar to that seen with lesions of the SPZ. Thus, release of TGF-α and PK2 from the SCN may act on nearby hypothalamic regions to inhibit the circadian rhythms of locomotor activity and wakefulness.

CLINICAL DISORDERS OF CIRCADIAN RHYTHMS The importance of circadian rhythms in humans is apparent to everyone who has worked a night shift or crossed several time zones. The pressure to sleep is often intense around one's usual bedtime, but even after remaining awake all night it can be difficult to fall asleep in the late morning. Because of this circadian promotion of wakefulness during the day, many shift workers have difficulty obtaining adequate amounts of sleep.

Abnormal timing of sleep is a common presentation of circadian rhythm disorders. Delayed Sleep Phase Syndrome is widespread in teens and young adults and helps explain the propensity of many young people to stay up late and then sleep late in the morning. Although this is sometimes a behavioral choice, for many it results from a delay in their endogenous rhythms that substantially interferes with morning activities. Exposure to bright light in the morning often helps entrain these individuals to a normal schedule.

For years, people believed that rising early in the morning was a matter of will power, but genetic studies have shown that genes involved in the timing of circadian rhythms play a critical role. Advanced Sleep Phase Syndrome (OMIM 604348) is uncommon, but can occur in families in an autosomal-dominant fashion. Affected individuals fall asleep around 7:30 PM and awaken around 4:30 AM and their rhythms of body temperature and melatonin are also advanced about 3–4 h. One affected family carries a mutation (S662G) in the *per2* gene that interferes with phosphorylation by casein kinase Iε. Deficient phosphorylation of this site

probably hastens the accumulation of PER2, thus, phase advancing its rhythm and producing very early bedtimes.

Polymorphisms in the *clock* gene also affect the timing of circadian rhythms. People with a C to T substitution at position 3111 in the 3′ UTR of the *clock* gene are more likely to be early risers. Unlike mice in which mutations in the coding region of *clock* produce large shifts in the timing of rhythms, this polymorphism only shifts preferred awakening times 10–44 min earlier. However, it clearly demonstrates the importance of CLOCK in the circadian regulation of human sleep.

NARCOLEPSY

CLINICAL FEATURES Narcolepsy (OMIM 161400) is characterized by chronic sleepiness and a marked disorganization of sleep/wake behavior. It commonly begins with mild to severe daytime sleepiness and unintentional naps in the teens and early twenties, though symptoms can begin in young childhood or after the age of 40. In contrast to sleep apnea and other disorders with poor quality sleep, the sleepiness of narcoleptics is often improved temporarily by a brief nap.

Narcoleptics usually have abnormal manifestations of REM sleep that intrude into wakefulness, including hypnagogic hallucinations, sleep paralysis, and cataplexy. Hypnagogic hallucinations are dream-like, often frightening hallucinations that typically occur with drowsiness or the onset of sleep. Sleep paralysis is profound weakness that occurs at the onset of sleep or on awakening. This is probably a persistence of REM sleep atonia into wakefulness, and during these episodes the individual feels awake but is unable to move. Cataplexy is sudden muscle weakness brought on by strong emotions, particularly joking, laughter, or anger. Most likely, this also is an intrusion of REM sleep atonia into wakefulness, but in contrast to sleep paralysis, cataplexy occurs almost exclusively in narcolepsy. Sixty percent of narcoleptics develop cataplexy, usually around the onset of sleepiness or within 3–5 yr.

The history alone is often very suggestive of narcolepsy, but a complete evaluation includes an overnight polysomnogram to exclude other causes of sleepiness followed by a multiple sleep latency test. During the daytime nap opportunities of the multiple sleep latency test, narcoleptics usually fall asleep in less than 5 min and have sleep-onset REM periods in two or more naps. Such daytime episodes of REM sleep are rare in normal individuals as REM sleep is under tight circadian control.

EPIDEMIOLOGY AND GENETICS Narcolepsy occurs in about 1 in 2000 individuals. Most cases occur sporadically, but genetic causes are likely to play an important role because first degree relatives have a 40-fold increased risk of developing narcolepsy. Nevertheless, these genetic factors are only a partial influence as even among monozygotic twins in which one has narcolepsy, the second twin is affected only about 25% of the time.

The most robust of these genetic factors are specific human leukocyte antigens (HLAs). Early studies using low resolution serological techniques found that narcolepsy is associated with two HLA class II antigens, DR2 and DQ1. This association varies with ethnicity; DR2 is found in 100% of Japanese, 90–95% of Caucasian, and 60% of African American narcoleptics with cataplexy. High resolution mapping of these regions demonstrated the existence of numerous alleles, and the 0602 allele of DQB1 (a DQ1 subtype), has been strongly linked with narcolepsy. DQB1*0602 is found in 88–98% of narcoleptics with unambiguous cataplexy, whereas it is found in only 12% of Caucasian American and 38% of African-American controls. Further susceptibility may be conferred by another allele, DQA1*0102, with an increase in risk when both DQA1*0102 and DQB1*0602 are present. A two- to fourfold increase in susceptibility is also seen in subjects homozygous for DQB1*0602. These associations do not prove an involvement of these alleles in the development of narcolepsy because the actual susceptibility could be because of nearby genes. However, extensive sequencing of this region has failed to reveal any new genes or narcolepsy linkages, suggesting that DQB1*0602 and DQA1*0102 directly influence the development of narcolepsy. Testing for DQB1*0602 can be helpful, particularly in individuals with questionable cataplexy, but this allele is hardly predictive of narcolepsy as over 99% of DQB1*0602 positive individuals do not have narcolepsy.

The genes for tumor necrosis factor (TNF)-α and the TNF receptor 2 also have been implicated in narcolepsy. TNF-α promotes sleep in laboratory animals, and *TNF*-α polymorphisms increase the risk of other HLA-linked diseases such as multiple sclerosis or systemic lupus erythematosis. The *TNF*-α gene sits within the HLA class III region on chromosome 6, and polymorphisms in the promoter regions of the *TNF*-α gene are associated with narcolepsy in Japan. A polymorphism in the *TNF receptor 2* gene on chromosome 1 also occurs more frequently among Japanese narcoleptics with cataplexy. This susceptibility appears especially strong among narcoleptics who have specific polymorphisms in both the *TNF*-α gene and the *TNF receptor 2* gene. Plasma TNF-α levels are normal in narcolepsy, but these polymorphisms may still affect TNF-α signaling, thus contributing to an autoimmune process or directly influencing the activity of sleep/wake regulatory pathways in the brain.

Familial narcoleptics are often DQB1*0602 negative and have an earlier onset of symptoms. The genes underlying these familial cases are generally unknown, but eight Japanese families with narcolepsy showed linkage to a site on chromosome 4p13-q21 that may act in concert with the HLA-influenced predisposition. Another family showed linkage to a site on chromosome 6 near the HLA region.

NEUROBIOLOGY OF OREXIN/HYPOCRETIN AND NARCOLEPSY Substantial evidence indicates that the neuropeptide orexin (also known as hypocretin) plays a critical role in the neurobiology of narcolepsy. One group named this peptide orexin for its presumed role in appetite, whereas another group named it hypocretin as a hypothalamic peptide with a resemblance to secretin. This peptide exists in two forms, orexin-A and orexin-B, which are derived from the same precursor and are colocalized in the same neurons. Orexin-containing neurons are found only in the lateral and posterior hypothalamus, but they project widely throughout the central nervous system (CNS), innervating the monoaminergic and cholinergic regions that promote wakefulness (Fig. 120-4).

The orexins are potent regulators of sleep/wake behavior. Injection of orexin into the CNS of rats increases wakefulness and markedly suppresses REM sleep. Orexin is released during wakefulness and acts through the type-1 and type-2 orexin receptors to directly excite neurons of the LC, DR, TMN, and PPT/LDT. Increased activity of aminergic arousal regions may directly promote wakefulness and inhibit the REM-producing cells of the LDT, thus stabilizing and sustaining wakefulness. Conversely, an absence of orexin signaling would weaken or otherwise alter the activity of the aminergic arousal regions, producing a destabilization of this circuit and abrupt fluctuations in behavioral state.

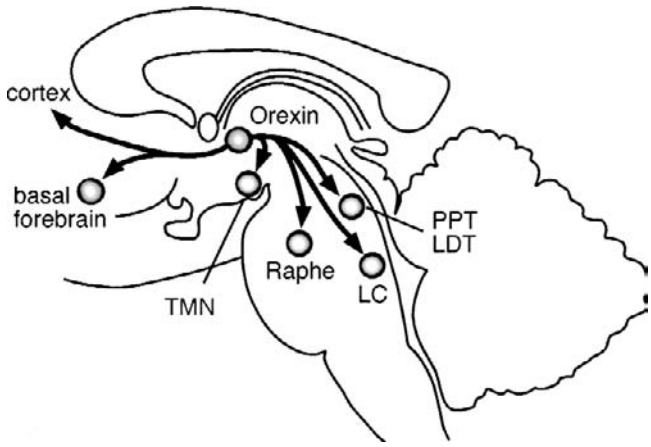

Figure 120-4 Orexin/hypocretin neurons in the lateral hypothalamus heavily innervate and excite many state-regulatory brain regions including the aminergic arousal regions, cholinergic PPT/LDT neurons, and basal forebrain. Orexin also may have direct effects on the cortex. LC, locus coeruleus; TMN, tuberomammillary nucleus.

IMPAIRED OREXIN SIGNALING CAUSES NARCOLEPSY After an extensive linkage analysis, mutations in the *orexin type-2 receptor* gene of dogs with autosomal-recessive narcolepsy were found. The more common mutation in these dogs probably produces a nonfunctional receptor because of skipping of exon 4. Simultaneously, other researchers found that orexin knockout mice have a phenotype strongly resembling human narcolepsy, with brief periods of wakefulness, rapid transitions into REM sleep, and behavior resembling cataplexy.

These studies demonstrated that congenitally impaired orexin signaling can produce symptoms of narcolepsy, but human narcolepsy is usually an acquired disease. To create a mouse model similar to human narcolepsy, mice were produced in which the orexin promoter drives the expression of ataxin-3, a truncated Machado–Joseph disease gene product that induces apoptosis in neurons. These orexin/ataxin-3 mice have a normal number of orexin neurons at birth, but as they reach adulthood, the orexin neurons degenerate. This acquired loss of orexin neurons roughly parallels the typical timing of human narcolepsy, and just as in humans, these mice cannot remain awake for long periods, rapidly enter REM sleep, and have behavioral arrests resembling cataplexy.

The importance of orexin in human narcolepsy has been established by several findings. About 90% of narcoleptics with cataplexy have no detectable orexin-A in their cerebrospinal fluid. Most likely, this is because of a loss of the orexin-producing neurons as 90% or more of the orexin neurons are absent from the brains of narcoleptics with cataplexy. This neuronal loss appears highly specific as other neurons in the same region are present in normal numbers.

Although this decrease in orexin is most likely because of a loss of the orexin-producing neurons, other causes are possible. One individual has been identified with a mutation in the *prepro-orexin* gene that probably produces inappropriate trafficking of the peptide. This exceptional patient has severe cataplexy and sleepiness that first became evident at the age of 6 mo. The adult onset of symptoms in the majority of narcoleptics makes orexin gene mutations an unlikely contributor in most cases, though a slow, degenerative process is possible. Alternatively, impaired transcription of the *prepro-orexin* gene could produce a loss of orexin without a loss of the orexin neurons. In support of this, a small number of narcoleptics may have a polymorphism in the 5′ untranslated region of the *prepro-orexin* gene, but this finding has not been confirmed by other studies. Many other polymorphisms have been identified in the *prepro-orexin* gene or in the genes coding for the orexin receptors, but none of these is linked with sporadic or familial narcolepsy. Thus, although some genetic factors such as HLA alleles clearly influence the occurrence of narcolepsy, mutations in the genes coding for orexin or its receptors are unlikely to be major contributors.

Narcolepsy is thought to result from an autoimmune or neurodegenerative process, but little evidence supports this idea. Markers of inflammation, analysis of spinal fluid, and neuroimaging are generally normal. Microglia and TNF-α mRNA are not increased in the brains of narcoleptics examined decades after the onset of symptoms, suggesting that there is no ongoing inflammation. The number of astrocytes may be moderately increased in the orexin neuron region, though one study found no gliosis. If supported by additional studies, this gliosis would be consistent with a neurodegenerative or inflammatory process.

These discoveries have markedly improved the understanding of narcolepsy with cataplexy, but the neurobiology of narcolepsy without cataplexy is still unknown. Narcoleptics without cataplexy are much less likely to carry DQB1*0602, and almost all have normal orexin levels. Possibly, these individuals simply have less extensive loss of the orexin neurons, with enough orexin production to stave off cataplexy, but the loss is still great enough to produce sleepiness and sleep-onset REM periods during their daytime naps. Alternatively, orexin may somehow be less effective in these individuals. Clearly, more research is needed to explain the varied causes of narcolepsy.

OTHER SLEEP DISORDERS RESULTING FROM CNS DYSFUNCTION

Landmark discoveries in the last few years have markedly improved our understanding of the molecular biology of narcolepsy and some disorders of circadian rhythmicity. This last section highlights other CNS sleep disorders for which new discoveries are beginning to reveal the underlying pathogenesis.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS OF SLEEP Restless legs syndrome (RLS) is characterized by nocturnal leg dysesthesias that are exacerbated by rest and relieved by movement or stretching. These uncomfortable sensations affect 10–20% of the population and can make it difficult to initiate or maintain sleep. Most patients with RLS also have periodic limb movements of sleep (PLMS) which are repetitive leg movements during NREM sleep. When they occur frequently, PLMS can disrupt sleep, producing mild to moderate daytime sleepiness.

Familial RLS usually begins before age 45 and is highly penetrant, often demonstrating an autosomal-dominant pattern. In some families, the disease may be recessive with linkage to chromosome 12q. Most cases of nonfamilial RLS results from iron deficiency, a peripheral neuropathy, or renal failure.

RLS and PLMS may be caused by brain iron deficiency and dysfunction of central dopaminergic pathways. Patients with RLS have low cerebrospinal fluid concentrations of iron, and iron levels are also low within the substantia nigra and possibly other brain regions. As iron is a necessary cofactor for tyrosine hydroxylase, this central iron deficiency may impair dopaminergic signaling. Dopamine agonists often improve RLS and PLMS, and dysfunction

of descending dopaminergic pathways that regulate spinal cord excitability may produce the dysesthesias and limb movements.

REM BEHAVIOR DISORDER Potent descending pathways normally inhibit motor activity during REM sleep, but in REM sleep behavior disorder (RBD), individuals vigorously act out their dreams, often resulting in injury. Although RBD is occasionally familial, it usually occurs in elderly men with synucleinopathies such as Parkinson's disease, multiple system atrophy, and dementia with Lewy bodies, as well as in narcolepsy, spinocerebellar ataxia type 3, and other diseases. RBD patients are often HLA DQw1 positive, but they do not have a high incidence of DR2. Neuropathological studies have yet to identify a consistent anatomic substrate, but identical behavior occurs in cats with lesions of the dorsal pons that interrupt descending inhibitory projections from the PPT/LDT to the medulla and spinal cord.

FATAL FAMILIAL INSOMNIA Most insomnia is caused by psychiatric or psychological disorders, but fatal familial insomnia (FFI; OMIM 600072) is characterized by progressive, severe insomnia in association with autonomic hyperactivity, dementia, and death within a few years. These rare patients often present with a striking loss of sleep, particularly deep NREM sleep, and in the later stages of the disease, they spend much of their time in a state of persistent drowsiness and dream-like hallucinations.

Like familial Creutzfeld–Jacob disease, FFI is produced by a D178N mutation of the *prion protein* gene that results in a protease-resistant prion protein. However, all FFI patients also have a 129M polymorphism that predisposes them to early severe insomnia, particularly with 129M homozygosity.

Pathologically, most cases have severe atrophy and gliosis of the anterior ventral and mediodorsal thalamic nuclei and olivary nuclei, with less substantial involvement of cortical and subcortical regions. Because the thalamus is essential in the generation of cortical slow waves, degeneration of this region may contribute to the intense insomnia of FFI. However, the insomnia also may be caused by injury to hypothalamic and brainstem regions.

NOCTURNAL FRONTAL LOBE EPILEPSY Nocturnal frontal lobe epilepsy begins around age 10 and is manifested by complex partial seizures that occur most commonly in light NREM sleep. The clinical spectrum ranges from paroxysmal dystonia to behavior resembling nightmares or sleepwalking.

Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE) is caused by mutations in the genes coding for the α- or β-subunits of the nicotinic acetylcholine receptor. In type 1 ADNFLE (OMIM 600513), the α4-subunit contains single nucleotide mutations (S248F, S252L) or a 3 base insertion that results in the addition of a leucine (L-776ins3). Type 2 ADNFLE (OMIM 603204) is linked to a site on chromosome 15 near the α3-, α5-, and β4-subunit genes. In type 3 ADNFLE (OMIM 605375), the β2 gene on chromosome 1 contains single base substitutions (V287L, V287M).

All of these mutations affect the transmembrane ionic pore region of the nicotinic receptor, but how these mutations produce seizures during sleep is unknown. α- and β-subunits assemble to form pentameric nicotinic channels, and the most common form in the brain is α4/β2. Most of these mutations increase receptor sensitivity to acetylcholine. Mice with gain-of-function mutations in the α4-subunit similar to the S248F mutation are more sensitive to the seizure-inducing effects of nicotine. Possibly, abnormal thalamo-cortical signaling during stage 2 NREM sleep triggers these seizures, but the precise electrophysiology is unknown.

FUTURE DIRECTIONS

Advances in the molecular biology of sleep disorders have shed light on the basic mechanisms of narcolepsy and other diseases, but many questions remain unanswered. Does an autoimmune or neurodegenerative process lead to orexin deficiency in narcolepsy? What is the cause of narcolepsy without cataplexy? What is the neurobiology of RLS and PLMS? Progress on these and other questions will improve understanding of these diseases and ultimately provide more effective therapies.

121 Neurofibromatosis 1 and 2

GREGORY J. ESPER AND DAVID H. GUTMANN

SUMMARY

Neurofibromatosis (NF) 1 and 2 are genetically and phenotypically distinct genetic disorders characterized by the development of benign and malignant tumors. Advances in molecular genetics have resulted in the identification of the *NF1* and *NF2* genes and their encoded proteins, neurofibromin, and merlin/schwannomin. Identification of these causative genes has led to an improved understanding of the molecular pathogenesis of NF1 and NF2, and has recently resulted in the development of targeted biologically based therapies for tumors in NF1. In this chapter, the epidemiology, clinical features, molecular pathogenesis, animal models, and therapeutic strategies for NF1 and NF2 will be discussed.

Key Words: Café-au-lait macule; juvenile cataract; meningioma; merlin; NF1; NF2; neurofibroma; neurofibromin; optic glioma; RAS; schwannoma; schwannomin.

INTRODUCTION

Neurofibromatosis (NF) 1 and 2 are genetically and phenotypically distinct diseases both characterized by the development of benign and malignant tumors. Advances in molecular genetics have resulted in the identification of the *NF1* and *NF2* genes and their encoded proteins, neurofibromin and merlin/schwannomin, respectively. Neurofibromin suppresses cell growth by downregulating RAS-GTPase mitogenic signaling, whereas merlin functions to negatively regulate cell growth and motility. Identification of these causative genes has led to an improved understanding of the molecular pathogenesis of NF1 and NF2, and has initiated the development of targeted therapies. This chapter discusses the epidemiology, clinical features, molecular pathogenesis, animal models, and therapeutic strategies for NF1 and NF2.

NEUROFIBROMATOSIS 1

EPIDEMIOLOGY NF1 is known also as peripheral neurofibromatosis or von Recklinghausen's disease, to recognize Frederick von Recklinghausen who first described the cellular component of the neurofibroma in 1882. NF1 is inherited in an autosomal-dominant fashion. Although complete penetrance is the rule, wide phenotypic variation occurs, such that some patients are only mildly affected, whereas others may be severely affected. The prevalence of NF1 has been estimated between 1/2190 and 1/7800. NF1 affects both genders and all races and ethnic groups equally. Despite its autosomal-dominant inheritance pattern, approx 50% of individuals with NF1 have no positive family history and likely represent new mutations.

The clinical manifestations of NF1 are mostly frequently recognized in early childhood, and are evident in nearly all affected patients by age 20. Although the majority of individuals with NF1 are relatively healthy, they exhibit increased morbidity and mortality compared to people without NF1, and they typically have life expectancies 10–15 yr less than unaffected individuals in the general population.

CLINICAL FEATURES The diagnosis of NF1 is based on the identification of two or more features from a defined list of NF1-associated clinical criteria (Table 121-1). Café-au-lait spots, skinfold freckling in the axillary, inguinal, and neck regions, and Lisch nodules or iris hamartomas are common pigmentary abnormalities. Cognitive dysfunction is also frequent, with more than 50% of affected individuals manifesting some form of specific learning disability. Skeletal dysplasia of the long bones or sphenoid ridge is distinctive in NF1, but much less common.

Tumors are among the most frequently observed manifestation of NF1. Benign peripheral nerve tumors, called neurofibromas, are seen in nearly all adults with NF1. Neurofibromas are Schwann cell tumors that grow from an associated nerve and contain other cell types, including fibroblasts and mast cells. In one-third of individuals with NF1, more diffuse neurofibromas (plexiform neurofibroma) that involve multiple nerve fascicles may be encountered. In contrast to discrete neurofibromas, plexiform neurofibroma tumors harbor a 5–10% lifetime risk for transformation into a malignant peripheral nerve sheath tumor (MPNST). MPNSTs occur in approx 8–13% of patients with NF1, and they are associated with a high mortality rate because they are poorly responsive to chemotherapy and radiation.

In addition to Schwann cell tumors, children with NF1 are at risk for the development of astrocytomas. Of children with NF1, 15–20% develop astrocytomas involving the optic pathway and hypothalamus. Continued growth of these tumors may result in visual loss, hydrocephalus, and hypothalamic dysfunction. Optic pathway gliomas are most frequently World Health Organization grade I pilocytic tumors. Typically, NF1-associated optic pathway tumors do not progress after 10 yr of age. Treatment is reserved for symptomatic tumors and most frequently involves carboplatin/vincristine chemotherapy.

Other cancers seen in individuals with NF1 include myeloid leukemias, myelodysplastic syndromes, and pheochromocytoma.

Table 121-1
Diagnostic Features for NF1

Two or more of the following features must be present for an individual to be diagnosed with NF1:
Six of more café-au-lait spots with diameters more than 0.5 cm before puberty or 1.5 cm after puberty
Two or more neurofibromas or a single plexiform neurofibroma
Freckling in the axillary and inguinal regions (Crowe's sign)
Optic pathway tumor
Lisch nodules (hamartomas of the iris)
A distinctive bony lesion: dysplasia of the sphenoid bone or dysplasia/thinning of long bone cortex
A first-degree relative diagnosed with NF1

Data from Gutmann et al., 1997.

There are significant psychosocial issues affecting individuals with NF1 that relate to physical appearance. The presence of numerous pigmentary lesions and neurofibromas can result in a significant cosmetic burden, which can be detrimental to a patient's self image.

MOLECULAR PATHOGENESIS The *NF1* locus spans 350 kb of genomic DNA on chromosome 17q11.2 and encodes a large gene, with more than 60 exons. The *NF1* protein, neurofibromin, is expressed in Schwann cells, neurons, astrocytes, myeloid cells, adrenal medulla, and oligodendrocytes. Inspection of the coding sequence of neurofibromin revealed striking sequence similarities between a small portion of neurofibromin and the catalytic region of a family of proteins termed GTPase-activating proteins (GAPs).

Subsequent studies have shown that neurofibromin functions as a GAP for the proto-oncogene RAS. When in its active form, RAS is bound to GTP and stimulates cell growth. The neurofibromin GAP-related domain functions to accelerate the conversion of active GTP-bound RAS to its inactive GDP-bound form. When neurofibromin is not expressed in NF1-associated tumor cells, dysregulated cell growth results from increased RAS activity (Fig. 121-1). In this regard, increased RAS activity has been associated with neurofibromin loss in tumors from NF1 patients, including leukemias, MPNSTs, and gliomas.

As is true for other tumor predisposition syndromes, individuals with NF1 start life with one mutated, nonfunctional *NF1* gene in every cell in their bodies. This is insufficient for tumor formation. Tumorigenesis requires a second inactivating mutation in the one remaining functional *NF1* gene to result in total loss of *NF1* gene expression. The combination of the germline *NF1* mutation and the subsequent acquired somatic *NF1* loss is termed the "two hit" hypothesis and explains why individuals with these inherited tumor predisposition syndromes are at high risk for tumor development.

Malignant tumors associated with NF1 involve additional genetic changes. In the case of the MPNST, a number of additional genetic changes are observed in addition to *NF1* inactivation, including inactivation of the p53 and p16 tumor suppressor genes as well as overexpression of the epidermal growth factor receptor.

ANIMAL MODELS OF NF1 The understanding of the molecular pathogenesis of NF1-associated tumors has derived from elegant studies in mice. Mice in which one copy of the *NF1* gene was mutated (*Nf1*+/– mice) are viable, but they succumb to malignant tumors (leukemia, lymphoma, and pheochromocytoma) at 15–18 mo of life. Although these mice do not develop the tumors typically associated with the human disorder, *Nf1*+/– mice exhibit specific learning disabilities, reminiscent of those found in children with NF1.

To develop mouse models of NF1-associated tumors, three approaches have been taken. First, mice have been generated in which some of their cells lack neurofibromin expression. These mice develop leukemias and plexiform neurofibromas. Second, *Nf1*+/– mice have been bred with *p53*+/– mice to generate *Nf1*+/–;*p53*/– mice. These mice develop high-grade MPNSTs that appear histologically similar to human MPNSTs. Lastly, to circumvent the embryonic lethality of *Nf1*–/– mice, mice have been generated that lack neurofibromin expression in specific tissues. These conditional *Nf1* knockout mice include those that lack neurofibromin in neurons, astrocytes, or Schwann cells. Neuron-specific *Nf1* inactivation results in abnormal neuronal function and extensive brain astrogliosis and cortical abnormalities. Astrocyte-specific *Nf1* conditional knockout mice have more astrocytes in their brains, but do not develop astrocytomas. Schwann cell-specific *Nf1* inactivation is also not sufficient for neurofibroma formation.

Recently *Nf1*+/– mice have generated in which either astrocytes or Schwann cells lack neurofibromin expression. These *Nf1* genetically engineered mice develop optic glioma and plexiform neurofibroma, respectively.

POTENTIAL THERAPIES Therapies focus on surgery and limited chemotherapies. As the understanding of the molecular pathogenesis of NF1 improves and robust preclinical animal models become available, the ability to offer more targeted, tailored therapies for NF1 may be possible. One explored treatment entails pharmacologic inactivation of RAS. RAS activation requires further post-translational modification by farnesylation of its CAAX sequence. Inhibition of this process using farnesyl transferase inhibitors results in inactivation of RAS, and theoretically, inhibition of cell hyperproliferation. This approach is in clinical trial for NF1.

NEUROFIBROMATOSIS 2

EPIDEMIOLOGY Also known as central or bilateral neurofibromatosis, the incidence of NF2 is between 1/33,000 and 1/87,000, based on two population studies from the United Kingdom and Finland. In the United States, there are about 100 new cases per year, though the prevalence is about 0.5 million people. In this respect, NF2 is 10-fold less common than NF1. Patients generally manifest clinical signs or symptoms by age 60, but most frequently present in their 20s. As is true for NF1, NF2 is transmitted in an autosomal-dominant fashion, and penetrance is almost complete.

CLINICAL FEATURES The most common clinical features of NF2 are bilateral vestibular schwannomas (VS). Schwannomas may also affect other cranial or peripheral nerves, but the vestibular nerve is the most frequently affected nerve. Bilateral VS or a family history of NF2 combined with any two of the other associated features, including meningioma, glioma, schwannoma, or cataracts, are criteria used to establish the diagnosis of NF2 (Table 121-2). Patients with unilateral VS and one of the aforementioned tumors, or patients with multiple meningiomas should also be evaluated for NF2. Manifestations begin by the third decade of life and are usually related to the site of origin of the tumor. For instance, vestibular tumors cause vertigo, tinnitus, and hearing loss. The "Wishart" and "Gardner" variants differ in severity, the former occurring in younger patients and behaving more aggressively because of multiple tumors, whereas the latter tends to occur later in life with a less severe clinical course. Mononeuropathy affecting the facial nerve is also a presenting feature, and can occur before VS are present.

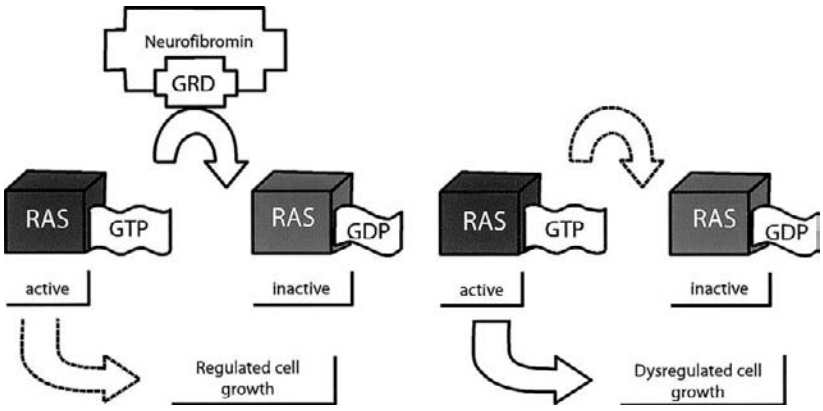

Figure 121-1 Neurofibromin and RAS regulation. Neurofibromin contains a central region of sequence homology shared with a family of proteins (GTPase activating proteins or GAPs) that accelerate the conversion of active RAS (bound to GTP to the inactive RAS-GDP molecule (left panel). Tight control of RAS activity results in regulated cell growth. In contrast, loss of neurofibromin results in increased RAS-GTP activity, facilitating cell growth and proliferation (right panel). GRD, neurofibromin GAP-related domain.

Table 121-2
Diagnostic Criteria for NF2

Confirmed (definite) NF2
Bilateral VS
Or
Family history of NF2 (first degree family relative) plus:
Unilateral VS at less than 30-yr-old, or
Any two of the following: meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities/juvenile cortical cataracts
Individuals to be evaluated for NF2 (presumptive or probable)
Unilateral VS at less than 30-yr-old, plus at least one of any of the following: meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities/juvenile cortical cataracts
Multiple meningiomas (two or more) plus unilateral VS at less than 30-yr-old, or
Any one of the following: glioma, schwannoma, juvenile posterior subcapsular lenticular opacities/juvenile cortical cataracts

Data from Gutmann et al., 1997.

There are few cutaneous pigmentary features compared with NF1. Three different types of skin tumors are present: an intracutaneous, raised, pigmented, plaque-like lesion, a subcutaneous nodular tumor manifesting on peripheral nerves, and intracutaneous tumors, thought to be schwannomas, similar to those in NF1. There are also prominent eye features, including optic nerve meningiomas, retinal hamartomas, and posterior lenticular opacities (juvenile cataracts).

MOLECULAR PATHOGENESIS The *NF2* locus spans 120 kb of DNA on chromosome 22q12.2. The *NF2* gene contains 17 exons that encode a 595 amino acid protein, termed merlin or schwannomin. Merlin is expressed in Schwann cells, neurons, lens fibers, blood vessels, and leptomeningeal cells. Analysis of the predicted protein sequence of merlin revealed striking sequence similarity to a family of proteins that link cell surface glycoproteins to the actin cytoskeleton. Merlin has homology to the ezrin, radixin, and moesin (ERM) subfamily of protein 4.1 molecules that contain three structural domains including the N-terminal (or FERM) domain, a predicted α helix, and a unique carboxyl terminal domain (Fig. 121-2A). Merlin is different from the ERM proteins, however, in that it does not contain the conventional C-terminal actin-binding domain present in ERM proteins, and it binds weakly to the actin cytoskeleton.

Consistent with merlin's proposed function as an ERM tumor suppressor, overexpression of merlin results in reduced cell growth and motility. Loss of merlin in schwannoma cells is associated with dramatic alterations in the actin cytoskeleton and merlin-deficient mouse tumor cells have a highly motile and metastatic phenotype.

Although the exact mechanism underlying merlin growth regulation is unknown, merlin associates with a number of important proteins that may impact on its ability to function as a negative growth regulator (Fig. 121-2B). In this regard, merlin binds CD44, sodium–hydrogen exchange regulatory factor, hepatocyte growth factor-regulated tyrosine kinase substrate, β-integrin, paxillin, syntenin, and schwannomin interacting protein 1. Further studies will be required to define the mechanism of merlin growth suppression.

ANIMAL MODELS OF NF2 The understanding of the molecular pathogenesis of NF2-associated tumors has derived from mouse modeling studies in which the *Nf2* gene has been inactivated in Schwann and leptomeningeal cells. *Nf2*+/– mice do not develop tumors associated with the human condition. To circumvent the early embryonic lethality of *Nf2*–/– mice, conditional *Nf2* knockout mice ($Nf2^{flox2}$) have been generated. $Nf2^{flox2}$; *P0*-Cre mice manifest Schwann cell hyperplasia, schwannomas, cataracts, and cerebral calcifications. Additional mice have been generated in which homozygous *Nf2* inactivation occurs in the leptomeninges by adenoviral-Cre delivery. These mice developed meningioma subtypes histologically similar to human meningioma subtypes.

POTENTIAL THERAPIES Management of NF2 is based on excision of tumors that result in hearing loss or other neurologic dysfunction. A combined medical and surgical approach by neurology, medical and radiation oncology, neurosurgery, otolaryngology, and other specialties is employed, and results are often better in centers with significant experience managing individuals with NF2. As the understanding of the function of merlin and its associated protein interactors improves, more promising therapies may be developed.

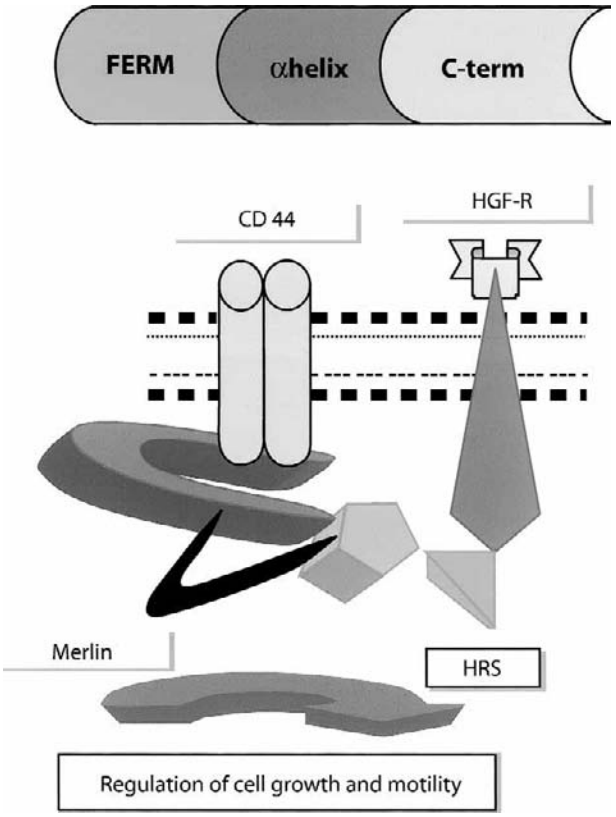

Figure 121-2 Merlin contains three predicted protein domains. **(A)** The FERM (four.1-ezrin-radixin-moesin) domain and the α-helical region are conserved among all ERM proteins, whereas the carboxyl terminus (C-term) is a unique region. **(B)** Merlin may regulate cell proliferation and motility by integrating mitogenic (cell growth) and motogenic (cell motility) signals emanating at the hyaluronic acid receptor (CD44) and hepatocyte growth factor receptor (c-met). Merlin has been shown to bind the cytoplasmic tail of CD44 and associates with one of the molecules (hepatocyte growth factor-regulated tyrosine kinase substrate) recruited by c-met activation.

CONCLUSIONS

Since the identification of the *NF1* and *NF2* genes, tremendous amounts have been learned of the normal function of neurofibromin and merlin relative to the pathogenesis of NF1- and NF2-associated features. Further research on the precise mechanisms underlying merlin and neurofibromin growth regulation will likely yield significant insights into targets for tailored drug design. The availability of robust mouse models for most of the NF-associated tumor features offers the exciting possibility of evaluating potential therapies in preclinical small animal models before testing in humans.

122 Axonal Regeneration and Recovery From Chronic Central Nervous System Injury

STEPHEN M. STRITTMATTER

SUMMARY

Damage to the adult brain or spinal cord commonly produces persistent dysfunction without recovery. To replace lost neurons, stem cells, trophic factors, and transplantation of neural-competent cells might be relevant. Treatment of dysfunction based on the disconnection of surviving neurons requires the axonal regeneration from remaining neurons and a degree of plasticity in neuronal connectivity. Those neurological conditions in which axonal regeneration and plasticity are most relevant are reviewed here. Recent scientific advances are likely to lead to the development of a novel group of therapeutics targeting axonal regeneration for the recovery of function in chronic neurological dysfunction.

Key Words: Axon; cerebrovascular accident; head trauma; multiple sclerosis; neural repair; Nogo; physical therapy; regeneration; spinal cord injury; stroke.

INTRODUCTION

Damage to the brain or spinal cord of adults commonly produces persistent dysfunction with limited recovery regardless of whether the insult is traumatic, ischemic, immunological, genetic, degenerative, toxic, metabolic, or nutritional in origin. One method to classify the basis of persistent deficits is cellular; either neuronal cell bodies are lost, or neurons survive but are functionally disconnected because of axonal or myelin loss. Therapeutic replacement or compensation for lost neurons poses a different problem than restoring functional connectivity between remaining neuronal populations. To replace lost neurons, stem cells, trophic factors, and transplantation of neural-competent cells might be relevant. Conversely, treatment of dysfunction based on the disconnection of surviving neurons requires the promotion of axonal regeneration from remaining neurons and a degree of plasticity in neuronal connectivity. This chapter reviews the neurological conditions in which axonal regeneration and plasticity are most relevant. Advances likely to lead to the development of a novel group of therapeutics targeting axonal regeneration for the recovery of function in chronic neurological dysfunction are summarized.

AXONAL DISCONNECTION AFTER CHRONIC CENTRAL NERVOUS SYSTEM INJURY

SPINAL CORD INJURY Axonal disconnection is most obviously the proximate cause of persistent disability after spinal cord injury (SCI). In the United States, approx 10,000 new cases occur each year, with a total prevalence of 250,000 individuals suffering disability from SCI. The two primary causes are motor vehicle accidents and gunshot wounds. Sporting accidents are the third most common cause. Most patients are young adults at onset and males are more commonly affected than females.

Spinal cord trauma selectively damages nervous system tissue at one to several spinal levels, but not throughout the cord. Although only a small segmental group of neurons are lost, functional deficits can be complete at all levels below the injury owing to the inability of descending motor and autonomic systems to connect with remaining caudal circuitry. Similarly, ascending sensory neurons caudal to the injury site might survive but cannot communicate with the supratentorial structures owing to axonal disruption. Functional axonal disconnection can result from both physical separation of distal axonal segments and from demyelination with conduction failure in remaining axons near the site of the trauma. It is clear that re-establishment of functional axonal connections between neuronal populations rostral and caudal to a SCI site is the most direct means of restoring function.

HEAD TRAUMA Head trauma with persistent deficits in motor or cognitive or emotional dysfunction is at least five times more common than spinal cord trauma. Pathophysiological mechanisms include skull fracture, epidural hemorrhage, subdural hemorrhage, and hydrocephalus. In addition, diffuse axonal injury secondary to acceleration/deceleration shearing of long axons in the forebrain is also recognized as a significant cause of long-term global cognitive dysfunction. In this case, multiple tracts in the subcortical white matter are disconnected and global functions dependent on interconnectivity are impaired.

STROKE Ischemic damage in the central nervous system (CNS) has multiple effects. A primary aspect of many "large vessel" hemispheral strokes is the loss of neuronal populations in discrete areas of the brain. Plasticity of remaining axonal connections is likely to play a critical role in the degree of functional recovery,

but the primary insult in these cases is not the axon. In contrast, most "small vessel" lacunar strokes occur in the white matter and, therefore, these events disrupt axonal connectivity to a greater extent than neuronal survival.

CHRONIC PROGRESSIVE MULTIPLE SCLEROSIS Recurrent immunological attack on CNS myelin is the principal pathophysiological process in relapsing remitting multiple sclerosis (MS). In chronic progressive MS, the accumulation of functional deficits is best correlated with axonal damage as sites of immunological myelin damage. Axonal retraction balls provide histological evidence for axonal interruption.

NATURAL HISTORY OF RECOVERY AFTER CHRONIC CNS INJURIES

MINIMAL IMPROVEMENT After traumatic SCI, the natural history of recovery follows a relatively predictable path. The level and distribution of injury in the cord determines the balance and distribution of motor deficits, sensory deficits, autonomic disturbance, and pain associated with the injury. On the American Spinal Injury Association clinical rating scale of functional performance from A (no function) to E (normal function), most patients improve by one point from their level at 3 d after injury to their level at 6 or 12 mo after injury. This modest improvement occurs over 1–6 mo but little further improvement, or decline, occurs after 6–12 mo. Few patients improve by two points, and essentially no patients improve by three or more points in large clinical studies.

The basis of the recovery that does occur spontaneously after SCI is not clear. It is unlikely to relate to axonal regeneration. More likely, plastic changes in the function and anatomy of uninjured circuitry are likely to account for enhanced clinical performance. For example, there are caudal intrinsic circuits in the spinal cord that can generate locomotor patterns. In tetrapedal vertebrates, the operation of these circuits in the absence of descending inputs can produce a degree of locomotion. This central pattern generator in the spinal cord of bipedal humans is less effective in the absence of descending input. However, modestly improved function might result from its enhanced function through anatomical plasticity in the months following an injury.

Clinical deficits after head trauma are much more variable than after SCI. However, the time-course for significant improvement matches the primary 1–6 mo window observed after SCI. Cognitive and emotional disturbances after head trauma are likely to improve to a greater extent than are motor deficits. This might reflect greater degrees of plasticity in these circuits.

Recovery from stroke is also variable but typically follows a time-course similar to the 1–6 mo course described earlier. It is not unusual for focal motor paralysis after lacunar strokes to completely resolve after several months, leaving only trace spasticity. Larger hemispheral strokes produce more persistent deficits, sometimes with minimal recovery of function. To the extent that recovery occurs, function appears to be redistributed to parallel pathways and/or to new alternate pathways. For example, partial recovery from the contralateral hemiplegia associated with a hemispheral stroke can involve activation of regions in the opposite, undamaged hemisphere. This shift of cerebral activity has been documented in functional MRI studies and if a second hemispheral stroke occurs contralateral to the first stroke, then recovered function is frequently lost. This redistribution is determined in large part by the age of the individual. Whereas robust in infants, plasticity is severely curtailed in adults. It is likely that both anatomic changes and altered electrical patterns in persistent connections account for these shifts in activation patterns during specific tasks.

Deficits in chronic progressive MS are by definition permanent. Continued disease activity and the accumulation of new lesions might be one explanation for the absence of recovery. In addition, the presence of widespread lesions is likely to limit compensation by parallel pathways.

PHYSICAL TRAINING Medical treatment to enhance recovery from chronic neurological injuries is severely limited. Physical and occupational therapy is the primary mode of treatment for the chronic deficits associated with the conditions described. Active physical therapy regimens do enhance the increase in functional status at 6 or 12 mo after one of these insults. The cellular or molecular mechanism by which this improvement occurs is not clear. The optimal form of training is also less than clear. Specific body weight-supported treadmill training has achieved much attention for SCI patients. Clinical trials to verify these benefits and optimize training regimens are underway.

PHARMACOLOGY No pharmaceutical agents are known to enhance the modest degree of functional recovery that occurs spontaneously and through optimal physical therapy. Some studies have suggested that amphetamines might enhance the benefits of physical therapy, but more definitive data are required to confirm or refute this effect. No pharmacological agents are in use to directly promote axonal regeneration or plasticity in the adult CNS after injury.

MOLECULAR DETERMINANTS OF AXON REGENERATION

EVIDENCE FOR EXTRINSIC DETERMINANTS *A priori*, one might imagine that adult CNS neurons have lost the capacity for axonal growth. However, adult mammalian CNS axons can grow extensively if their environment is altered. Transplantation of sciatic nerve segments into various regions of the CNS is followed by dramatic axonal growth into the peripheral tissue. Although cell-autonomous factors might limit the rate of maximal axonal regeneration in the CNS, extrinsic factors play a critical role in preventing axonal regeneration after SCI, head trauma, stroke and chronic progressive MS (Fig. 122-1).

GROWTH PROMOTING FACTORS IN THE PERIPHERY Extrinsic controls on adult CNS axon regeneration might include the presence of inhibitory factors limiting growth and the absence of factors that promote growth. Neurotrophic axon-growth promoting factors that are not expressed at adequate levels in the CNS to promote robust regeneration are potentially numerous. For specific neuronal populations, nerve growth factor (NGF), brain-derived neurotrophic factor, neurotrophic-3 play some role in regulating short-range sprouting in the adult CNS. However, data suggest that the neurotrophic factors alone cannot support long-distance axonal growth in the adult CNS. Glial-derived neurotrophic factor family ligands and gp130 cytokines have also been implicated in regulating the axonal growth potential of certain adult neurons. Although these factors clearly regulate the potential for growth, they appear inadequate to explain the great disparity between rapid peripheral nerve regenerative extension and absent CNS axonal regeneration.

INHIBITORS IN CNS: ASTROCYTES AND OLIGODENDROCYTES The presence of axon growth inhibitors in the adult CNS appears to play a more prominent role in limiting axonal regeneration after injury. Growth inhibitors can be separated as CNS myelin-derived or astrocyte glial-scar derived. The astrocytic

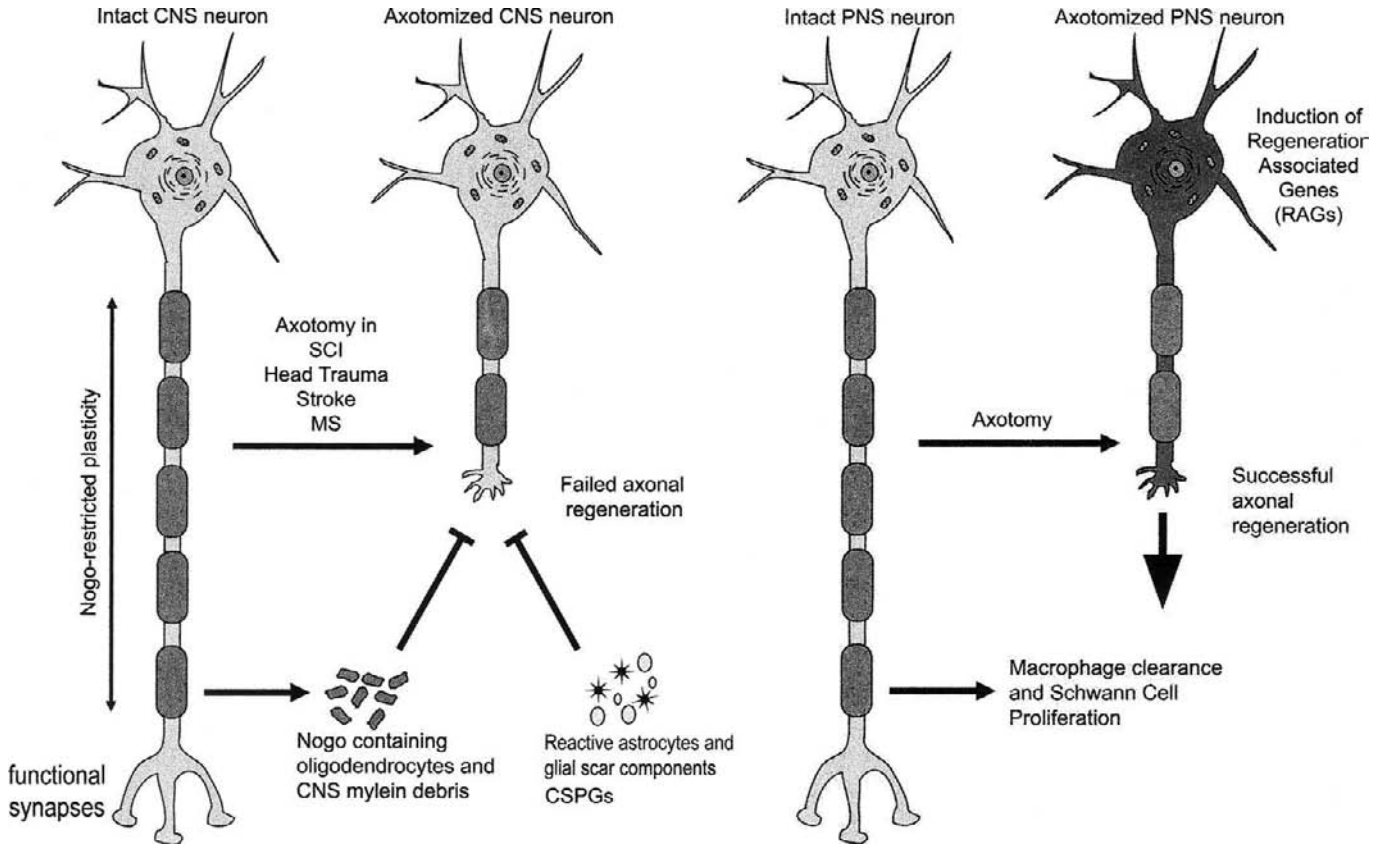

Figure 122-1 Molecular determinants of axonal regeneration and recovery from axotomy. Axonal regeneration after CNS injury is limited by CNS myelin and astrocytic scars. Regeneration-associated genes activated during peripheral nerve regeneration fail to be induced after central axotomy.

glial reaction is localized at the site of injury whereas myelin inhibition might be widespread and play a role in regulating CNS plasticity in the absence of injury. Although CNS oligodendrocyte-derived myelin is inhibitory of axonal growth in vitro, peripheral nervous system (PNS) Schwann-cell-derived myelin is much less of an impediment for axonal growth.

OVERCOMING CNS INHIBITION OF AXONAL GROWTH: GLIAL SCAR

CHONDROITIN SULFATE PROTEOGLYCANS Astrocytic scar tissue in sections or in tissue culture limits axon growth. Several products of the astrocyte are implicated in mediating this inhibition. Most prominent are a class of proteoglycans containing chondroitin sulfate (Fig. 122-2). Astrocytes also secrete the inhibitory extracellular matrix (ECM) protein tenascin. The chondroitin sulfate proteoglycans (CSPGs) exist in secreted, ECM-bound and cell surface forms and include Neurocan, Phosphocan, neuroglian 2, Aggrecan, and others. Immobilized CSPGs can inhibit axonal growth in tissue culture and, in vivo, those CNS axons that do not regenerate are frequently observed to be halted at a zone of increased CSPG. There is evidence that the glycosaminoglycan side chains of these molecules are the primary determinant of their inhibitory activity. However, the exact determinants of activity regarding side chain length, diffusibility, and structure are not well defined.

SIGNALING MECHANISMS Although an axonal cell surface receptor for CSPGs has not been described, there is evidence that they limit axonal growth by activating an intracellular signaling protein, Rho (*see* Fig. 122-2). Rho is a GTP-binding protein that is active in the GTP-bound state and plays a prominent role in regulating filamentous actin cytoskeleton dynamics. CSPG exposure activates Rho in neurons. Activated Rho signals to the cytoskeleton through a Rho-associated kinase, ROCK. In this regard, axonal growth inhibition by astrocytic CSPG and oligodendrocyte myelin-derived inhibitors converge on one pathway (*see* Fig. 122-2). Inhibition of either Rho or ROCK stimulates axon growth in vitro and overcomes axon inhibition by CSPGs.

TREATMENT OPTIONS Two methods have been developed in preclinical studies to perturb astrocytic CSPG inhibition of axon regeneration. The first involves digesting the CSPGs with a bacterial enzyme, chondroitinase. The second method is to inhibit Rho or ROCK activity. Both methods reportedly alleviate some CNS inhibition and promote anatomical axonal regeneration of some fibers and behavioral recovery in rodent SCI studies. Regeneration is by no means complete in these studies, but the regeneration of a small portion of axons has pronounced effects on locomotor recovery. To the extent that different methods can be compared, the results are similar to those observed with various myelin perturbations described in the next section.

OVERCOMING CNS INHIBITION OF AXONAL GROWTH: CNS MYELIN

NOGO In defining the molecules underlying the inhibition of adult CNS axonal regeneration by CNS myelin, protein fractionation and molecular cloning identified Nogo (*see* Fig. 122-2).

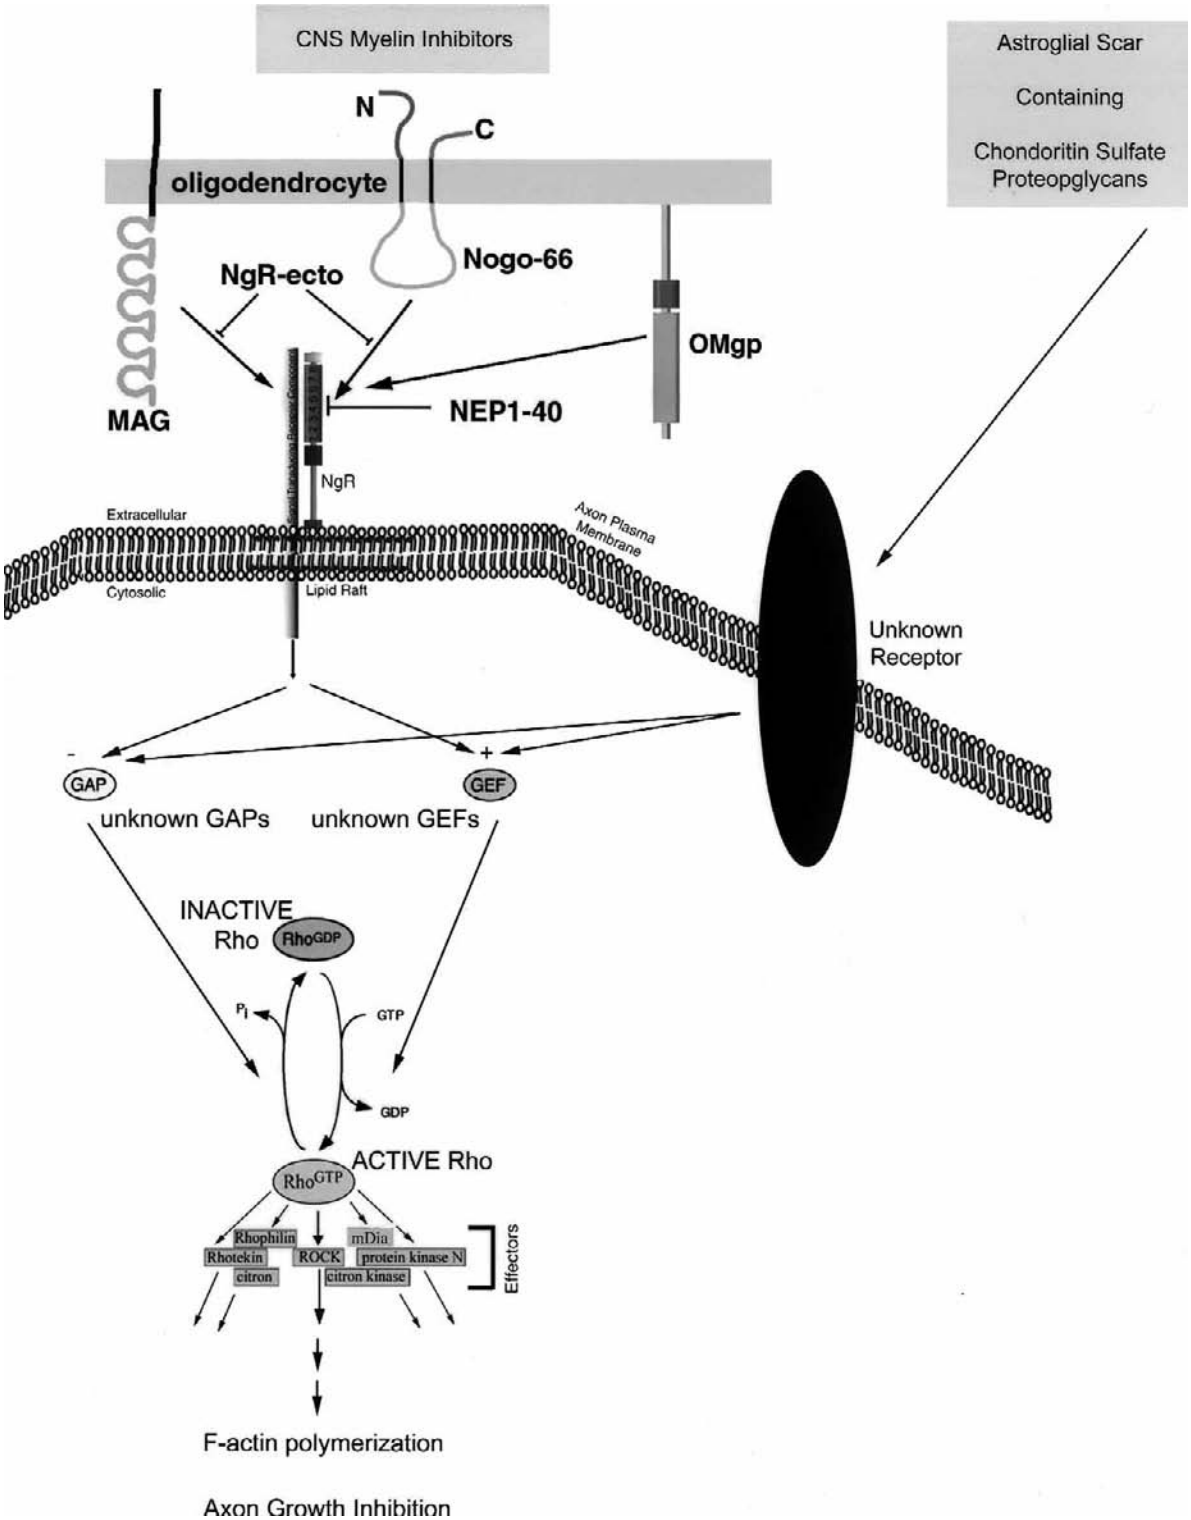

Figure 122-2 Molecular pathways limiting axonal regeneration and points of intervention. The myelin proteins, Nogo, MAG, and oligodendrocyte myelin glycoprotein bind to an axonal Nogo-66 receptor to limit axonal regeneration in the CNS through Rho/ROCK activation. CSPGs produced at high concentrations in glial scars also inhibit CNS regeneration by activating the Rho pathway. MAG, myelin-associated glycoprotein; GAP, GTPase-activating protein; GEF, guanine nucleotide exchange factor; NEP1-40; NgR, Nogo-66 receptor; OMgp, oligodendrocyte myelin glycoprotein.

Nogo is a member of the reticulon family of genes, which appear to play a role in endoplasmic reticulum function in neurons and endocrine cells. All reticulons have two hydrophobic domains and no signal sequence, suggesting that the amino and carboxyl termini might be located in the cytoplasm. Nogo (or reticulon 4) exists in three isoforms derived from alternate splicing and promotor usage.

Only Nogo-A of the reticulon family has been detected in the oligodendrocyte in which a fraction of the protein reaches the cell surface rather than being confined to the endoplasmic reticulum. Peripheral Schwann cells do not express Nogo, providing a molecular basis for the selectivity of axonal regeneration.

Recombinant purified Nogo protein has two inhibitory domains, termed Amino-Nogo and Nogo-66. The Nogo-66 domain specifically inhibits axonal growth, whereas the Amino-Nogo domain acts to inhibit cell spreading from multiple cell types as well as axonal outgrowth. Nogo-66 action is mediated by the Nogo-66 receptor (NgR) described later. The mechanism of Amino-Nogo action is not known. CNS myelin lacking Nogo is much less inhibitory for axonal growth in culture, suggesting that Nogo accounts for much of the inhibitory activity of CNS myelin. Significant degrees of axonal regeneration and functional locomotor recovery after SCI have been observed in some mouse strains lacking the Nogo-A/B isoforms.

MYELIN-ASSOCIATED GLYCOPROTEIN Alternative protein fractionation methods applied to CNS myelin led to the recognition that a second protein, myelin-associated glycoprotein (MAG), is also inhibitory for axonal growth. MAG, an immunoglobulin superfamily protein with a single transmembrane domain, is found on the surface of myelinating cells and localized in perinodal regions. The relative importance of MAG vs Nogo is not entirely clear. Because MAG is expressed in both the peripheral and central myelin fractions its expression does not correlate with regenerative potential, suggesting that it might be less relevant than Nogo-A. However, the MAG expression in Schwann cells might be compensated by a more rapid clearance of MAG in the periphery than in the CNS during Wallerian degeneration. The fact that mice lacking MAG do not show evidence for CNS axonal regeneration after SCI demonstrates that MAG is not necessary to prevent CNS axonal regeneration.

OLIGODENDROCYTE-MYELIN GLYCOPROTEIN By focusing selectively on the glycosyl phosphotidylinositol (GPI)-linked proteins of CNS myelin, investigators identified a third axonal growth inhibitory protein, termed oligodendrocyte myelin glycoprotein (OMgp). OMgp is a leucine-rich repeat cell surface protein, attached to the plasma membrane through a GPI lipid anchor. This inhibitor is selectively expressed in the CNS, and is found in both neurons and oligodendrocytes. No genetic studies of OMgp's role in axonal regeneration in vivo have been reported.

RECEPTOR MECHANISMS NgR was identified as a necessary mediator of Nogo-66 neuronal binding and axonal inhibition (*see* Fig. 122-2). NgR is expressed only in mature neurons and localizes to axons. The protein is made up of eight leucine-rich repeats of defined structure and the polypeptide is anchored to the plasma membrane through a GPI lipid moiety. After NgR was identified as a mediator of Nogo-66 action, it became clear that the protein also mediates the action of MAG and OMgp through high affinity binding. Thus, one receptor is the focus of action for three CNS myelin-derived axonal growth inhibitors. In the human genome there are two NgR-related genes, but neither protein encoded by these genes interacts with myelin inhibitors.

SIGNALING MECHANISMS Because the NgR is GPI-anchored to the outside of the plasma membrane, it is not immediately obvious by what means signals are transduced to the cell interior in order to limit axonal growth. The most possible mechanism for signal transduction is a second receptor subunit that functions in transduction but not ligand recognition. For some neurons, the p75-NTR low affinity NGF receptor might play this role, but the role of p75-NTR in axonal regeneration has not been examined in vivo. Although the mechanisms by which myelin inhibitory signals reach from the NgR to the cytoplasm is not completely clear, NgR signals activate the GTP binding protein Rho and its downstream kinase ROCK inside of the neuron. This provides a point of convergence between inhibitory signaling by myelin and scar-derived CSPGs (*see* Fig. 122-2).

TREATMENTS TARGETING MYELIN-BASED INHIBITION Because the molecular basis of CNS myelin inhibition of adult axonal regeneration is defined molecularly, several opportunities for intervention have been developed. One method is to mask the inhibitors with antibodies. Either antiNogo antibodies or immunization with myelin to generate auto-antibodies has been effective in producing a degree of axonal regeneration and functional recovery after experimental SCI. Given the possibility that immunoreactivity to myelin might produce MS or experimental allergic encephalitis-like side effects, the determinants of beneficial and deleterious myelin immunoreactivity will have to be explored carefully. A variant of the antimyelin antibody method that has produced axonal regeneration in rodent models is the CNS delivery of autologous macrophages or dendritic cells primed with myelin in vitro in order to clear myelin and promote regeneration.

The NgR is a prime target for intervention to promote axonal regeneration because it is an extracellular neuronal protein and a focal point for the action of three inhibitory ligands in myelin. A peptide antagonist of the NgR has been identified that blocks Nogo action in vitro. In vivo, this peptide promotes the regeneration of descending corticospinal tract fibers and raphe spinal fibers after experimental rodent SCI. The axonal regeneration is accompanied by significant functional improvement in locomotion. The therapeutic time window is broad for this compound, with high effectiveness when treatment is begun at 1 wk postinjury. Furthermore, this compound is effective when administered systemically, accessing the spinal cord through an interrupted blood–brain barrier during the weeks after SCI. NgR antagonists that block the action of MAG and OMgp as well as Nogo at the NgR might have even greater effectiveness. Soluble fragments of the NgR itself can serve as decoy receptors blocking all three myelin inhibitors, and are likely to be more efficacious in vivo than the Nogo-selective NgR peptide antagonist.

The myelin inhibition system might also be blocked at the level of intracellular signaling through the Rho-ROCK pathway. Small molecule ROCK antagonists have been identified, and are in development for therapeutic use in humans. The advantage of this method for promoting axonal regeneration and functional recovery is that CSPG inhibition might be blocked as well as myelin inhibition. The disadvantage is that Rho and ROCK are expressed in many cell types and unwanted side effects might occur. ROCK inhibitors have produced a degree of axonal regeneration and functional improvement in rodent SCI studies.

OVERCOMING CNS INHIBITION OF AXONAL GROWTH: TRANSPLANTATION

SCHWANN CELLS The sciatic nerve transplantation studies make clear that the peripheral nerve environment is conducive to CNS axonal regeneration, suggesting that transplantation of isolated Schwann cells into sites of CNS axotomy might alter the environment and allow long-distance growth of axons to improve recovery. This altered environment might include the masking of inhibitors, the substitution of a noninhibitory environment and the secretion of growth-promoting factors. It is clear that transplanted Schwann cells

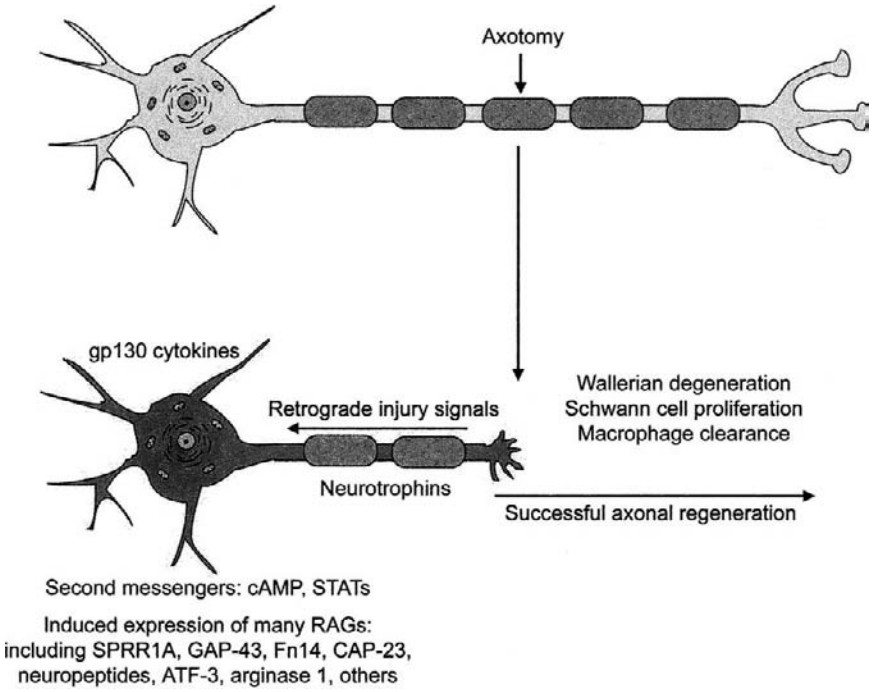

Figure 122-3 Regeneration-associated genes and pathways promoting axonal regeneration of recovery of function. In the PNS, regeneration-associated gene products such as GAP-43, CAP-23, galanin, SPRR1A, and Fn14 are induced by axotomy and support rapid axonal regeneration. Cytokine, neurotrophin, and cAMP signaling play roles in supporting rapid axonal outgrowth.

can promote a degree of axonal regeneration and can myelinate injured axons in rodent SCI models. To a somewhat lesser extent, regenerating axons leave a site of transplantation to enter the uninjured CNS to provide functional connections. Although any transplantation methodology raises issues related to rejection, there is a possibility that autologous transplantation from expanded cultures of peripheral Schwann cells from the sural nerve might avoid this issue.

OLFACTORY ENSHEATHING CELLS The olfactory system is unique in the adult mammalian CNS in that axons continue to possess regenerative capacity in the adult. Rather than Schwann cells or oligodendrocytes, primary olfactory neurons are surrounded by a specialized olfactory ensheathing cell (OEC). When transplanted into adult rodent SCI sites, the OEC survives and migrates into surrounding uninjured tissue. Several laboratories have documented dramatic axonal regeneration and remyelination of injured axons after OEC transplantation in rodent SCI. Even after chronic complete spinal transection injuries, OEC transplantation is reported to improve substantially the degree of functional recovery in rodent locomotion. Human trials of OEC transplantation are being conducted in China.

BIOPOLYMERS Bioengineering has the potential to provide synthetic materials with axonal growth promoting surfaces and with diffusible growth-promoting factors that might bridge a CNS axotomy site. Numerous versions of such materials are being developed. Although many such polymers might promote growth, a major unresolved obstacle is that axons growing into a graft must leave the graft and reenter inhibitory CNS tissue if they are to perform any useful function.

PROMOTING THE GROWTH POTENTIAL OF CNS NEURONS

REGENERATION-ASSOCIATED GENES Apart from the preferential expression of inhibitory myelin and scar inhibitors in the CNS, the differential growth of CNS and PNS neurons is explained in part by cell-autonomous factors. After PNS injury, but not after CNS injury, changes in gene expression within injured neurons support robust axonal regeneration, irrespective of extracellular factors (Fig. 122-3). One demonstration of this principle comes from "preconditioning" peripheral nerve lesions. If a sciatic nerve axotomy precedes a SCI by a few days, then the central process of the sensory neuron that was previously injured in the periphery exhibits a marked degree of axonal regeneration at the SCI site. It is clear that the peripheral injury induces changes in second messengers and gene expression in the dorsal root ganglion neurons that allow CNS growth.

A number of genes exhibit altered expression after peripheral nerve injury. Among the regeneration-associated gene products (RAGs) that alter the growth state of the sensory neuron are GAP-43, CAP-23, SPRR1A, Fn14, *galanin*, *arginase* I, and HSP-27. It is unclear if the enhanced expression of one or more of these genes is sufficient for CNS axonal regeneration in vivo. There are data that combined transgenic expression of GAP-43 and CAP-23 can drive a limited degree of CNS axonal growth under certain circumstances in the CNS. It might be that multiple genes must be expressed coordinately to fully mimic the rapid growth of peripheral neurons.

SIGNALING MECHANISMS Several signaling cascades have been demonstrated to participate in the enhanced growth state of the "preconditioned" growth state and to contribute to enhanced axonal growth. cAMP is present at high levels in developing neurons and decreases postnatally, only to be increased selectively after peripheral axonal injury. Pharmacological elevation of cAMP increases the growth of axons in culture on permissive and nonpermissive substrates. Furthermore, in vivo elevation of cAMP levels in sensory neurons allows a degree of sprouting and growth at SCI sites. These changes might be mediated at least in part through the induction of arginase I expression and increased polyamine levels.

Cytokines of the gp130 class, including LIF and IL-6, are increased in the stump of an injured peripheral nerve and in vitro application promotes axonal growth in vitro through Stat-dependent signaling. In vivo studies with knockout mice support the notion that these cytokines play a critical role in rapid peripheral axonal regeneration and contribute to the "preconditioning" effects. Because these cytokines have prominent roles in immunological responses and axonal regeneration, it is not obvious how they might alter recovery if administered locally in the brain or spinal cord.

TREATMENT OPTIONS The potential for mimicry of peripheral gene expression and second messenger changes as a therapeutic modality is large, but untested in most cases. Methods for increasing the function of individual RAGs are not well developed so in vivo data about their ability to increase CNS regeneration are few. Methods to promote cAMP and thereby enhance the growth state of neurons have received the most attention. At least for ascending sensory fibers, acute cAMP elevation appears to produce some local sprouting of injured fibers. Rolipram is a cAMP phosphodiesterase type 4 inhibitor developed originally as an antidepressant that might be most useful in testing the efficacy of this mode of therapy.

CONCLUSION

Axonal disconnection plays a major role in the persistent disability following a number of CNS injuries of traumatic, ischemic, and immunological nature. For many years, the possibility of promoting recovery from these injuries by axonal regeneration has been considered to be nil. This pessimism has been relieved by the scientific developments described. It is reasonable to suggest that rational molecular therapies will someday be employed to improve recovery. The molecular understanding of the limits on the axon regeneration process has advanced rapidly. Moreover, it has led to several methods for promoting adult CNS axonal regeneration in preclinical studies. Enhancement of axonal regeneration can be considered a novel therapeutic target for recovery from SCI, head trauma, stroke and chronic progressive MS. Treatment modalities might be developed to reduce the effectiveness of myelin inhibitors such as Nogo, MAG and OMgp acting at the NgR and of the glial scar containing CSPG inhibitors. Alternatively, enhancement of the intrinsic growth state of neurons by increasing the expression or function of RAGs might be effective. Cell transplantations might have the capacity to alter the CNS environment and support maximal axonal regeneration. Because these different potential treatments attack semi-independent mechanisms, they might have synergistic effects on improving recovery from chronic CNS axonal disconnection.

XIV. PSYCHIATRY

$5HT_{1A}$	serotonin receptor
5HT1b	serotonergic autoreceptor
5HTT	serotonin transporter
ACC	anterior cingulate cortex
ACTH	adrenocorticotropic hormone
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazole propionate
ASD	acute stress disorder
AVP	arginine vasopressin
BDNF	brain-derived neurotrophic factor
BDZ	benzodiazepine
BNST	bed nucleus of the stria terminalis
BPD	borderline personality disorder
CC	corpus callosum
CCK	cholecystokinin
CCK-4	cholecystokinin tetrapeptide
Cdk5	cyclin-dependent kinase 5
CENTG2	centaurin γ-2
CNS	central nervous system
CPZ	chlorpromazine
CREB	cAMP response element-binding protein
CRF	corticotropin-releasing factor
CRH	corticotropin-releasing hormone
CRHR1	corticotropin-releasing hormone receptor 1
CSF	cerebrospinal fluid
DA	dopamine
DARPP-32	dopamine and cAMP-regulated phosphoprotein 32
DAT	DA transporter
DRD3	dopamine receptor D3
DSM-IV	*Diagnostic and Statistical Manual of Mental Disorders*
EAA	excitatory amino acid
EEG	electroencephalographic
FDG	fluorodeoxyglucose
FMRP	Fragile X mental retardation protein
GABA	γ-aminobutyric acid
GAL	galanin
GAP	GTPase-activating protein
GR	glucocorticoid receptor
GRKs	G protein receptor kinases
HPA	hypothalamic–pituitary–adrenal
HVA	homovanillic acid
LC-NE	*locus ceruleus*-based noradrenergic
LTP	long-term potentiation
MAO-A	monoamine oxidase A
MAOIs	monamine oxidase inhibitors
MAP1B	microtubule associated protein 1B
MeCP2	methyl-CpG-binding protein 2
MHC1-R	melanin-concentrating hormone receptor
MR	mineralocorticoid receptor
NAc	nucleus accumbens
NE	norepinephrine
NK-1	neurokinin 1
NMDA	*N*-methyl-D-aspartate
NPY	neuropeptide Y
OCD	obsessive-compulsive disorder
OTR	oxytocin receptor
PCP	phencyclidine
PDD-NOS	pervasive developmental disorders not otherwise specified
PDE	Phosphodiesterase
PFC	prefrontal cortex
PKA	protein kinase A
PP-1	protein phosphatase 1
PTSD	posttraumatic stress disorder
PVN	paraventricular nucleus
rCBF	regional cerebral blood flow
RGS	regulators of G protein signaling
SERT	serotonin transporter
SMC	sensorimotor control
SNPs	single-nucleotide polymorphisms
SNRIs	selective norepinephrine reuptake inhibitors
SRR	sibling relative risk
SSRI	selective serotonin reuptake inhibitor
SSRIs	selective serotonin reuptake inhibitors
V1aR	vasopressin receptor
V1b	AVP receptorWnt w/e
VTA	ventral tegmental area of the midbrain

123 Molecular Mechanisms Regulating Behavior

Focus on Genetic and Environmental Influences

KERRY J. RESSLER AND CHARLES B. NEMEROFF

SUMMARY

This chapter outlines how the preclinical fields of molecular biology and neuroscience are converging to allow for meaningful answers relevant to the molecular foundations of psychiatry. Advances over the next decades will undoubtedly provide novel and powerful tools that advance the treatment, if not cure, of devastating psychiatric disorders that not that long ago were thought to be untreatable. This introduction will examine how molecules act at different organizational levels within the brain to influence behavior. Specifically, this chapter examines how both genetic and environmental influences can alter the molecular milieu of individual neurons, discrete neural circuits, and neuromodulation throughout the brain.

Key Words: Anxiety; behavior; corticotrophin releasing factor; environment; Fragile X; gene; oxytocin; psychiatry; serotonin; synaptic plasticity; vasopressin.

INTRODUCTION

Perhaps the most complicated problem in biology is how molecules, interacting through the laws of physics, create complex behavior in animals. The molecular mechanisms that create thought, emotion, self-awareness, and consciousness in humans seem impossibly complex, and yet progress is being made. This chapter outlines how the preclinical fields of molecular biology and neuroscience are converging to begin to allow dissection of these questions in ways that provide meaningful answers relevant to the molecular foundations of psychiatry. Such advances over the next decades will undoubtedly provide novel and powerful tools that advance the treatment, if not cure, of devastating psychiatric disorders previously thought to be untreatable.

The following chapters outline first how to approach complex genetic mechanisms in psychiatry followed by discussion of the current state of knowledge regarding the molecular and genetic bases of depression, anxiety, schizophrenia, autism, post-traumatic stress disorder, and addictive disorders. This chapter examines how molecules act at different organizational levels within the brain to influence behavior and how both genetic and environmental influences can alter the molecular milieu of individual neurons, discrete neural circuits, and neuromodulation throughout the brain.

The external environment, through various mechanisms combined under the term "stress," is known to affect the risk of psychiatric disease. However, the relative roles of environment and genetics have been heatedly debated. The pendulum of thought in psychiatry has swung from an entirely environmentally based process with the more extreme views of psychoanalysis, to a sometimes extreme biological determinism view of genetics in the latter half of the 20th century. The fields of psychology, behavioral neuroscience, molecular neuroscience, and genetics are now sufficiently advanced that a rapproachment may be possible, in which whether nature vs nurture determines behavior is no longer the question. Instead, acceptance that both clearly do create an exciting series of questions in examining, through their molecular mechanisms, "How do genes and environment work together to create behavior?"

THE COMPLEXITY OF BRAIN AND BEHAVIOR

The biological rules that govern brain function are uniquely complicated compared with other organ systems because of the biological complexity of the brain (it expresses more of the total genetic information encoded in DNA than any other organ in the body) and because the brain is continuously being molded by the environment. In fact, the most critical function of the brain may be to alter itself, i.e., to learn, through interaction with the external environment.

Furthermore, brain function cannot be inferred directly from neuronal function. This is in contrast with most other organ systems within medicine in which molecular medicine = cellular medicine = medicine. This is because in most organs, the function of the organ straightforwardly represents the function of its component cells. For example, a molecular understanding of hepatocytes or cardiac myocytes readily leads to direct predictions regarding the physiology and pathophysiology of the liver and heart, respectively. In contrast, although the brain includes neurons and glia, and the function of neurons and glia is understandable, that understanding alone does not directly reveal brain function.

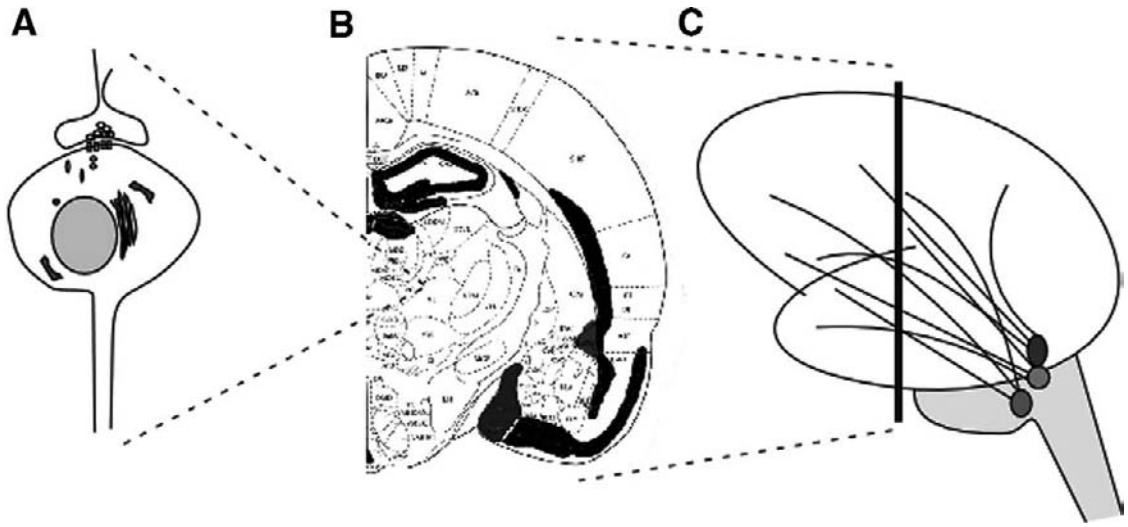

Figure 123-1 Levels of brain organization. This schematic diagram illustrates different levels of neuronal and brain organization that must be appreciated to understand the molecular mechanisms by which genes and environment influence behavior. **(A)** Cellular biology of individual neurons as well as the molecular mechanisms mediating formation and maintenance of the synapse (specialized cellular connections that permit rapid transfer of information between neurons). **(B)** Discrete neural systems perform separate functions and express different sets of genes as illustrated by this coronal section of a rodent brain in which a subset of different brain regions are highlighted. **(C)** Modulation of the different neural systems within the brain occurs at a whole brain level in part owing to neuromodulatory neurotransmitters that are released from mid-brain nuclei such as the raphe nucleus that releases serotonin, the ventral tegmental area that releases dopamine, and the locus ceruleus that releases norepinephrine.

This dissociation between neuronal cellular function and behavior occurs for several reasons. As mentioned, the complexity of gene expression in the brain is as complex as the remainder of the body. This results from genetic heterogeneity among hundreds of different types of neurons and supporting glial cells. Furthermore, groups of different neurons are molecularly, anatomically, and functionally clustered such that it may be sometimes more useful to consider each nucleus in the brain as a separate functional "organ system." For example, the striatal system appears to mediate motor learning and coordination, the amygdala system mediates fear and other emotions, and the hippocampal system mediates multiple aspects of memory formation. Even with this perspective, the complexity of these discrete brain nuclei is still more than the molecules and genes that compose them because of the nearly infinite combination of neuronal connections that occur between the 100 billion neurons and their 100 trillion synapses in the human brain.

Therefore, an effort to understand molecular mechanisms of behavior actually requires an effort to understand multiple levels of functional organization:

1. How molecules mediate individual neuronal function and connectivity.
2. How molecules influence processing of information within discrete nuclei.
3. How molecules modulate interaction between neurons and brain regions in the formation of behavior.

An understanding of the physiology and pathophysiology of behavior thus requires an integration of molecular and systems level neurobiology.

MOLECULAR MECHANISMS OF BEHAVIOR OCCUR AT MULTIPLE LEVELS OF BRAIN ORGANIZATION To understand the genetic and environmental mechanisms by which molecules affect behavior, the primary levels of organization that are differentially influenced must be clarified (Fig. 123-1). This section outlines how molecules influence cellular connectivity, regional brain specialization, and neuromodulation of multiple brain circuits. Table 123-1 summarizes the examples described below of how both genes and environmental influences are able to act through different molecular mechanisms to result in similar physiological and pathophysiological outcomes at each level of organization. These examples illustrate the multiple complex, yet eventually understandable, mechanisms by which genes and environment may interact to regulate behavior.

INFLUENCES ON NEURON FUNCTION AND CONNECTIVITY: THE ROLE OF SYNAPTIC PLASTICITY

The principle cellular function of the neuron is to receive chemical and electrical neural signals and to pass similar signals to other neurons. As with all cell types, a large variety of ion channels and pumps, neurotransmitter receptors, growth factor receptors, transcription factors, and other molecules are required for normal cellular functions. In addition to these proteins, the neuron also requires specialized machinery for the development, maintenance, and ongoing plasticity of its synapses, the specialized cellular regions in which signals are transmitted from one neuron to the next (Fig. 123-1A).

The ability to form, maintain, and eliminate synapses has tremendous importance for animal behavior. These cellular functions provide the underpinnings of learning and memory and, thus, the basis for animals to react to situations based on previous experience. Evidence suggests that cellular synaptic plasticity can be modulated by both genetic and environmental influences. One method to examine synaptic plasticity in the brain involves the visualization of synaptic spines, the dendritic specializations for synaptic inputs (Fig. 123-2A). Evidence suggests that with learning and following periods of enhanced synaptic plasticity, the number, size, and shape of synaptic spines are altered on neurons that are undergoing neural plasticity. The following two examples illustrate genetic and environmental mechanisms by which synaptic spine regulation is altered contributing to altered synaptic plasticity.

Table 123-1
Genetic Bases for Behavior

Level of organization	*Gene function (example)*	*Behavioral function*	*Genetic influence*	*Environmental influence*	*Associated disorder*
Intracellular/synaptic plasticity	FMR-1/FMRP is involved in dendritic translation and synaptic plasticity	Learning and memory	CGG expansion diminishes FMRP production and leads to immature spines	Enrichment enhances FMRP production and synaptic spine density	FMR1 mutation leads to Fragile X inherited mental retardation
Regional brain function	OTR/V1aR regional patterns of expression influence level of parental care and pair bonding	Social memory and behavior	Promoter polymorphisms lead to different expression patterns	Maternal Care influences levels of expression in different brain regions	Alterations in levels of oxytocin or OTR are implicated in autism and affective disorders
Central modulation of neuronal activity	5HT transporter removes synaptic 5HT 5HT1b is a 5HT autoreceptor	Behavioral state	5HTT "l" vs "s" Polymorphism. Short allele diminishes 5HTT expression	Acute stress increases 5HT1b receptor expression	Increased risk for anxiety and depression have been shown with short promoter allele of 5HTT

FRAGILE X, A GENETIC MECHANISM OF IMPAIRED PLASTICITY Fragile X syndrome is the most common form of inherited mental retardation, occurring in 1:4000 males and 1:8000 females. It is characterized by a cluster of signs in addition to mental retardation, including stereotyped facial features, macroorchidism, and abnormalities in attention and short-term memory. The disorder is now known to result from an unstable trinucleotide repeat within the gene that leads to variable lengths of repeats in different individuals. The presence of 5–50 repeats of the nucleotide sequence "CGG" leads to normal Fragile X mental retardation protein (FMRP) function. Longer series of repeats, in some individuals as many as 200 repeats, lead to a "premutation" that is still without phenotype. But in the next generation, a dramatic expansion of the repeat region occurs that is up to several thousands of nucleotides, leading to the full phenotype of Fragile X mental retardation. This occurs owing to the lack of functional FMRP.

FMRP is known to encode a mRNA binding protein that serves as a chaperone to carry mRNA from the nucleus to the cytoplasm. This function is important for many mRNAs, but particularly for dynamically regulated mRNAs such as the mRNA for microtubule associated protein 1B (MAP1B). MAP1B is one of many proteins implicated in the normal synaptic plasticity mechanisms required for normal synaptic spine function. Absence of FMRP is thought to lead to inappropriate or dysregulated MAP1B expression at the dendritic synapse, which may contribute to dysregulated synaptic plasticity, and abnormalities in dendritic spines that occur in Fragile X syndrome (Fig. 123-2B,C). The inability to form normal mature synaptic spines likely leads to dysfunctional neuronal communication in the brain and may underlie the short-term memory, attentional, and cognitive deficits seen in Fragile X syndrome.

EARLY ENRICHMENT: AN ENVIRONMENTAL MECHANISM OF ENHANCED PLASTICITY Results from several experiments suggest that following a learning event, there may be enhanced neural plasticity to alter the structure and synaptic contacts of neurons involved in this plasticity. In fact, animals that have an enriched and complex environment during development have a higher synaptic spine density in certain cortical areas than animals that were raised in standard housing containing minimal sensory stimulation. Animal data consistently shows that early enrichment leads to more plastic brains and more dendritic spine density (Fig. 123-2D).

What leads to this increased density of synaptic spines? Early environmental enrichment likely enhances the availability of a neurotrophic growth factor in the brain, brain-derived neurotrophic factor (BDNF), which has been implicated in enhancing the learning process and synaptic spine density in certain brain areas. Furthermore, clinical depression has been associated with lowered BDNF levels in certain regions of the brain, and data suggest that the complex phenotype of depression results partly from lowered synaptic plasticity during the depressed phase. Certain animal models of depression also are characterized by decreased BDNF concentrations, and early environmental enrichment appears to partially prevent depression-like phenotypes in those animals.

INFLUENCES ON REGION-SPECIFIC BRAIN FUNCTION: THE ROLE OF NEUROPEPTIDE SPECIALIZATION

Regional circuits contribute to specific brain functions resulting in distinct behaviors. Some genes, such as the homeobox family and other similar transcription factors, act during development to determine regional brain specialization. Differential gene expression in the adult contributes to the specialized connectivity and function of different brain regions. Despite this developmental determination of regional function, the levels and patterns of expression of certain genes can still be influenced by environmental experience. The following examples of genetic and environmental control of regional gene expression involve the vasopressin receptor (V1aR) and oxytocin receptor (OTR) genes. These neuropeptide receptors have significant influence on sexual and social behavior, and are implicated in the stress response and the biology of depression.

GENETIC CONTROL OF REGIONAL NEUROPEPTIDE RECEPTOR EXPRESSION DETERMINES SEXUAL BEHAVIOR Exclusive mating for life between a male and female of the same species is called pair bonding. This occurs in some monogamous species, whereas other species are entirely polygamous. How does this difference arise? One particularly powerful model of pair bonding is the vole, a rodent species slightly larger than a mouse. Remarkably, behavioral scientists observing animal behavior in the

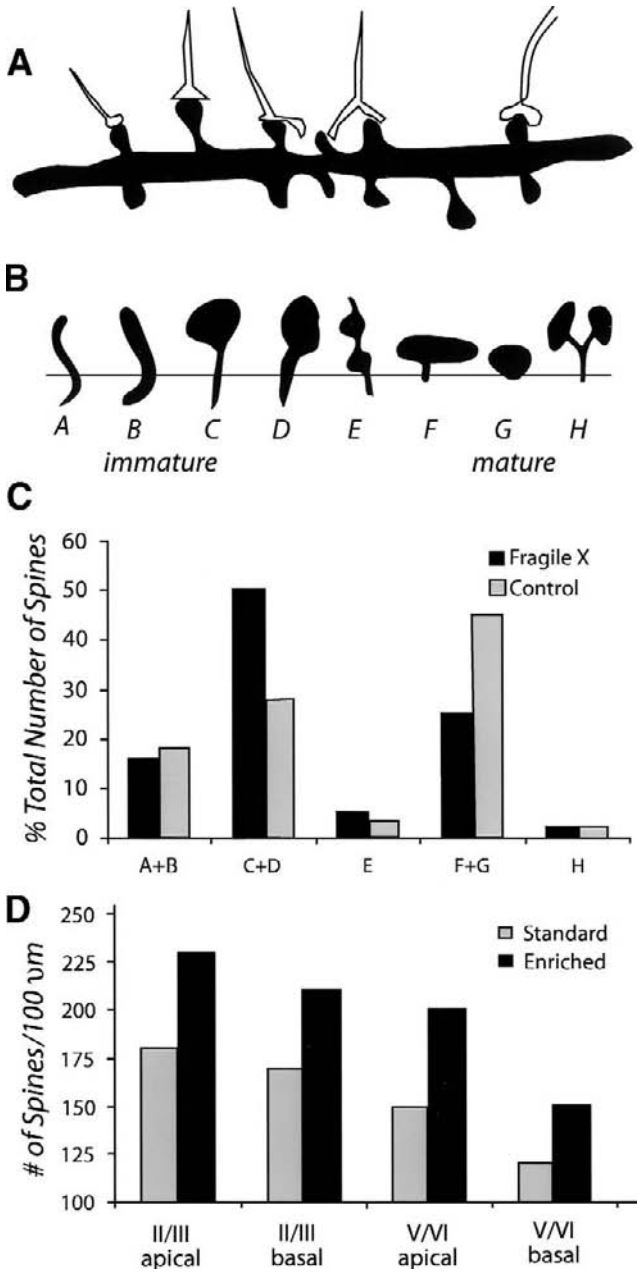

Figure 123-2 Development of synaptic spines as a marker of synaptic plasticity. **(A)** Schematic illustration of the many synaptic contacts (on the order of 1000 per neuron) that occur between presynaptic axon terminals connecting onto synaptic spines of a region of a pyramidal neuron dendrite within the brain. **(B)** Synaptic spines have different morphologies at different times following their induction as illustrated by spines A–H. **(C)** Graph illustrating the relative immaturity of synaptic spines in Fragile-X syndrome as compared to control human brains (B,C adapted from Greenough et al. 2001 with permission.). **(D)** Total number of synaptic spines in different layers of cortex (II, III, V, VI) of rats that were housed in standard conditions vs those housed in enriched environments. (Adapted from Johansson and Belichenko, 2002 with permission.) This illustrates the enhancement of synaptic connectivity that occurs with environmentally enriched stimuli.

wild noted that one species (the prairie vole) pair bonded, whereas a very similar species (montane vole) was highly polygamous. Gene expression was examined in the brains of these animals looking for correlations between pair bonding and gene expression. Although the animals were almost identical in their genomes and in their brain expression pattern, they exhibited one critical difference. In males, it is known that the neuropeptide vasopressin is critical for sexual behavior and is released with mating, whereas in females, the neuropeptide oxytocin has a similar role. In the brains of the monogamous species, the V1aR in males and the OTR in females was found to be highly expressed in a region of the brain called the ventral striatum or nucleus accumbens, an area known to be involved in appetitive learning and reward (Fig. 123-3A). In contrast, the polygamous species had similarities in patterns of vasopressin and OTR expression in many areas of the brain, except for the ventral striatum, in which there was very little or no receptor expression.

Further experiments suggest that this differential expression pattern may lead to a conditioned learning event following mating. Thus the monogamous animals may associate their partner as a highly rewarding neural signal whereas the polygamous animals do not undergo that conditioning event. This difference in expression pattern is in part because of variation in the promoter regions of these receptors. These results imply that genetic control of regional expression of neuropeptide receptors can exert profound effects on the behavioral state of the organism.

Oxytocin is likely involved in many social behaviors in addition to pair bonding. Autism is a highly genetic disorder that involves profound disruption of social learning. Autism has recently been suggested, at least in some cases, to involve disruption within the oxytocin system.

ENVIRONMENTAL CONTROL OF NEUROPEPTIDE RECEPTOR EXPRESSION BY VARIATION IN MATERNAL CARE

Despite the previously mentioned data that neuropeptide receptor expression, specifically the OTR, is highly genetically controlled, there is now considerable evidence that environmental signals also exert control over expression of this receptor during development. In addition to its role in pair bonding, OTR levels may be involved in differential sensitivity to experimental measures of anxiety as well as other social behaviors. Numerous environmental effects have been identified that influence social behavior and anxiety measures. One of the most interesting and clinically relevant models is of variations in maternal care. Within the same species of lab rats, there are individual variations in levels of maternal nurturing as measured by licking, grooming, and nursing behaviors. Adult offspring of mothers that were observed to have high levels of nurturing maternal care (e.g., high levels of licking/grooming and arched-back nursing), are consistently found to appear less anxious in numerous behavioral models, even though there are no obvious differences in health, weight, or other general physical measures.

Their data suggest that such variation in maternal care lead to early developmental changes in gene expression within the brain. In fact OTR levels in females and V1aR levels in males are increased within the central nucleus of the amygdala in offspring of more nurturing mothers (Fig. 123-3B). It is important to note that these variations in maternal care can be entirely different based on early environmental exposure, independent of genotype. Cross-fostering studies show that animals raised by highly nurturing foster mothers are more social, less anxious, and express more OTR or V1aR than do those raised by less nurturing foster or natural mothers. These findings suggest that variations in maternal care may influence the expression of oxytocin and vasopressin in a gender-specific manner. Although the genetic mechanisms have not yet been elucidated, it is likely that such dynamic regulation of these neuropeptide receptors involves both genetically determined promoter polymorphisms and

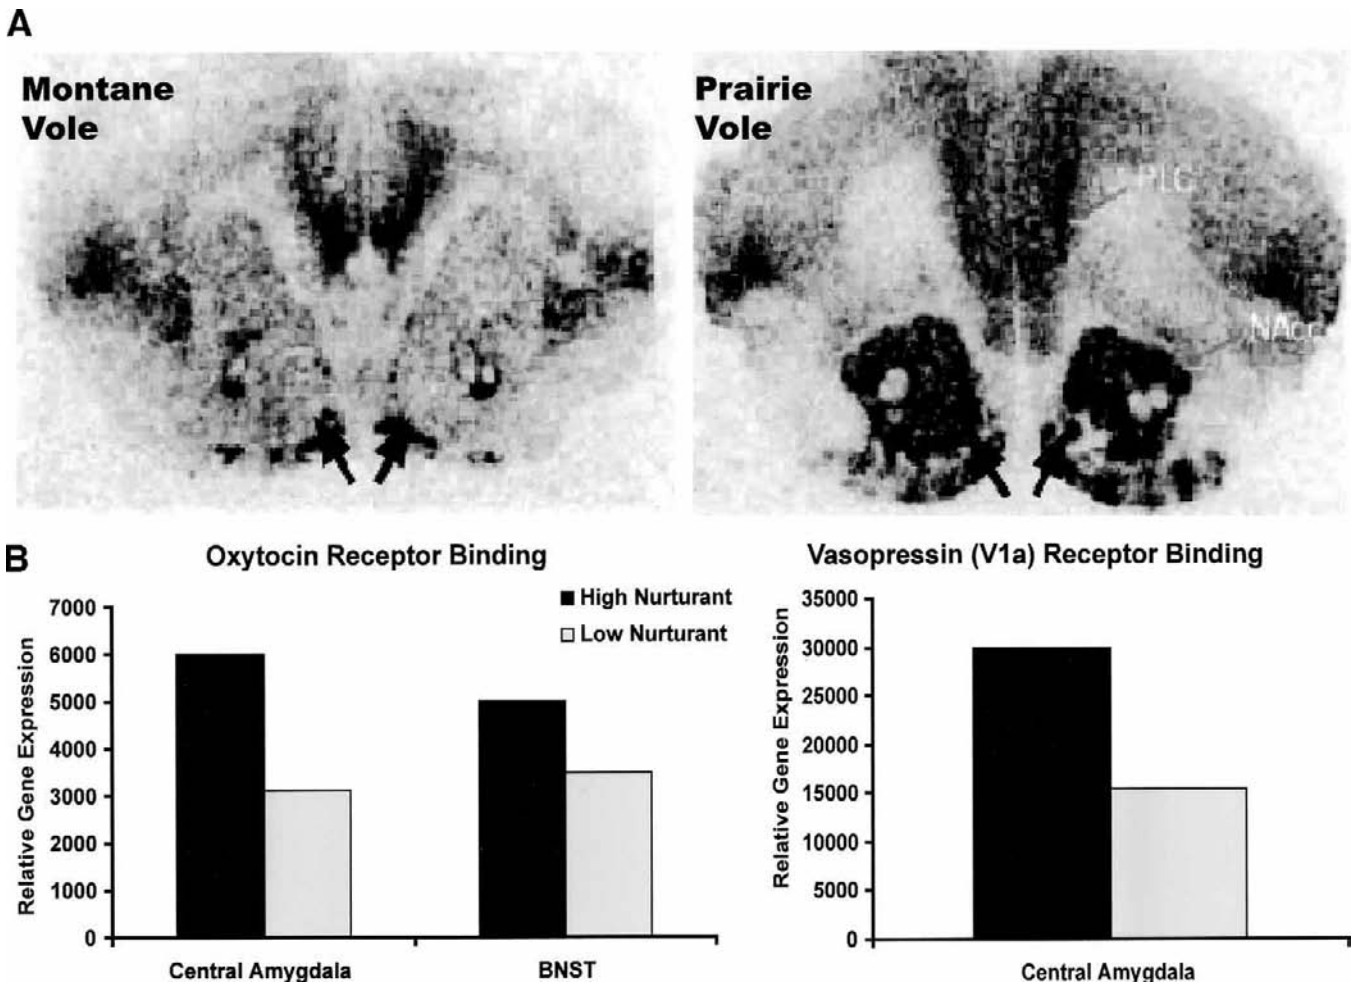

Figure 123-3 Oxytocin and vasopressin receptor expression in specific brain regions. **(A)** Figure showing expression of the oxytocin receptor, as demonstrated with receptor binding autoradiography, in the polygamous montane vole or the monogamous prairie vole. This genetic control increased receptor expression in the nucleus accumbens, a brain region important in reward, is thought to contribute to the monogamous sexual behavior of the prairie vole. (Adapted from Insel and Young, 2001.) **(B)** Total level of oxytocin receptor in female rats (left graph) or vasopressin receptor in male rats (right graph) is partially a function of rearing environment. The animals raised by mothers that were highly nurturant (as indicated by increased licking, grooming, and arched-back nursing behavior), had offspring with higher levels of oxytocin and vasopressin receptor gene expression in the central amygdala and nucleus of the stria terminalis (BNST), two regions implicated in emotional and social learning and behavior. (Adapted from Francis et al. 2002.)

environmentally determined molecular factors that provide modulatory control over the expression of these receptors.

INFLUENCES ON NEUROMODULATORY CIRCUITS: THE ROLE OF CENTRALLY ACTING NEUROTRANSMITTERS

This chapter has focused on the roles of individual neuron function and connectivity and the importance of regional gene expression in contributing to behaviorally important functions. The broadest mechanism by which genes and molecules can influence behavior is through action at the level of the entire brain. In fact the majority of psychiatric medications are active at this level—on the neuromodulatory neurotransmitters, specifically monoamines such as serotonin, norepinephrine, and to a somewhat lesser extent, dopamine. These three neurotransmitter systems are similarly organized anatomically, with their primary releasing neurons located in the midbrain, and their axonal projections reaching throughout the entire brain. The regulated firing of these modulatory systems has tremendous impact on "states" of brain function such as level of arousal, attention, sleep/wake, vigilance, or relaxation. Central neuromodulation of multiple brain circuits occurs to coordinate activity of different brain regions and circuits. Genes determine aspects of this modulation, yet the *tone* of these systems is regulated through environmental experience.

Although there are many different neuropeptide and neurotransmitter modulatory systems within the brain, the following examples illustrate how the serotonin transporter and a specific serotonin receptor are regulated. Serotonin is produced by the raphe nuclei within the midbrain and is released by raphe neuronal projections throughout the brain. Serotonin neurotransmission is clearly dysregulated in depression and anxiety-related disorders. In general, cerebrospinal fluid measurements have revealed decreased concentrations of serotonin, or its major metabolite, 5-hydroxy-indoleacetic acid. There is also evidence of brain alterations from postmortem studies and functional brain imaging studies in serotonin receptor binding in depression. In general,

antidepressants enhance serotonergic transmission by a variety of mechanisms throughout the brain. Although serotonin clearly has many functions, one of its roles is the proper modulation of limbic circuits, including the hippocampus and amygdala, during the experience of emotional stimuli. Alterations in the serotonin system, both in the raphe neurons and in target postsynaptic neurons can have profound effects on emotional behavior.

GENETIC CONTROL OF SEROTONIN TRANSPORTER EXPRESSION INFLUENCES ANXIETY The primary mechanism of action of the selective serotonin reuptake inhibitor antidepressants is binding and inhibiting the serotonin transporter (5HTT). The 5HTT protein is located primarily on presynaptic nerve terminals, and plays a critical role in removing serotonin from the synapse and thus in terminating the neurotransmitter signal. Selective serotonin reuptake inhibitors, through inhibiting this transporter, initially enhance serotonin release throughout the brain. After several weeks of treatment with this class of medication, the serotonergic system shows altered firing patterns. It is thought that this long-term adaptation is integral for the antidepressant effect.

Studies examining polymorphisms of the 5HTT gene have revealed interesting aspects of its regulation and potential effects of this regulation on mood and anxiety disorders. The long (l) variant of a promoter polymorphism within the 5HTT gene is more than twice as active as the short (s) variant. This is because of differences in 5HTT mRNA synthesis and expression resulting from the promoter polymorphism. Increased anxiety traits and increased traits of "neuroticism" are associated with the less active "s" allele. Furthermore in some studies, the response to antidepressant treatment is different in patients with homozygous "s" alleles such that patients with the "s" allele are more resistant to antidepressant treatment. Another approach to examining antidepressant function has been to deplete the availability of the amino acid tryptophan, a precursor to serotonin, during the treatment response period on antidepressants. Patients with the "s" allele of 5HTT are more likely to experience a rapid return of depressed symptoms during tryptophan depletion than are patients with the more active "l" allele. Through such mechanisms of altered promoter regulation of 5HTT, genetic control over the central serotonergic modulatory system can significantly influence risk for depression and anxiety, as well as response to treatment.

ENVIRONMENTAL REGULATION OF SEROTONIN RECEPTORS IN ANIMAL MODELS OF STRESS Through genetic knockout models and by examination of levels of receptor expression, the serotonergic autoreceptor (5HT1b) has also been implicated in response to stress and antidepressant action. The 5HT1b receptor is located on presynaptic axon terminals of raphe neurons and is involved in regulating serotonin release onto target neurons. Decreased 5HT1b binding intensity has been demonstrated in cortex, hippocampus, and septum after acute stress in rats. These changes were seen in conjunction with decreased 5HT1b mRNA expression in the dorsal raphe nucleus.

5HT1b expression was measured within the dorsal raphe nucleus in two different rodent models of differential stress sensitivity, congenital learned helplessness and maternal separation. The congenital learned helplessness model involves the development of two lines of rats through differential breeding that are either highly susceptible or resistant to developing learned helplessness. Learned helplessness is a model in which rats receive repeated inescapable shocks resulting in behavior that appears less active and socially withdrawn and is accompanied by neurochemical indicators of depression. It is an often-utilized model of depression that exhibits antidepressant responsiveness.

Maternal separation is another widely-used model in which rat pups are removed from their mother for 3 h daily from postnatal d 2–14. As adults, these animals are then compared on a number of behavioral measures with controls that were removed from their mother for only 15 min daily over the same time period. This maternal separation paradigm leads to reproducible behavioral effects mimicking depression and anxiety in the adult. Interestingly, the animals removed for only 15 min daily appear to have more resistance to depressive symptoms following stress than do control (animal facility reared) animals. This suggests that such environmental models may model risk for depression following stress, but may also provide a model of resilience.

A number of molecular studies have been performed with the learned helplessness and maternal separation models of depression. These studies have clearly demonstrated that chronic inescapable stress leading to learned helplessness as well as early alterations in maternal care can both have profound effects on the molecular milieu within the brain. In particular, the levels of 5HT1b-receptor expression have been examined in both of these models of depression. There are differences in levels of 5HT1b-receptor expression in acutely stressed animals vs unstressed animals, suggesting that there are rapid changes in serotonin receptor levels in the aftermath of environmentally induced stress. Receptor levels were also examined in both models of stress-resilience, the line of rats that is resistant to learned helplessness and the rat pups that experienced 15 min of maternal separation. Both models of stress resilience showed elevations in levels of 5HT1b-receptor gene expression compared to the stress-sensitive controls. These results suggest that there are differences in 5HT1b levels in animals that are sensitive vs those that are resilient to stressful situations.

The two different approaches also provide for interesting interaction between genetic differences (as seen in the congenital learned helplessness lines) or environmental insult (maternal separation) and environmental stress experienced in adulthood. It is remarkable that the genetic model exhibiting lowered activity of 5HTT and the environmental model with less 5HT1b may both result in similar neural phenotypes—decreased feedback control of serotonin levels at the synapse.

ENVIRONMENTAL REGULATION OF CORTICOTROPIN-RELEASING FACTOR IN ANIMAL MODELS OF STRESS Another neuromodulatory neurotransmitter that clearly shows environmental regulation is the corticotropin-releasing factor (CRF) neuropeptide. There is abundant evidence that CRF and related peptides are the primary CNS mediators of stress. Stress generally is defined as extraordinary demand on the organism or alterations in psychological homeostatic processes. Initially its importance was thought to be primarily endocrine via activation of adrenocorticotropic hormone from the pituitary, with subsequent release of cortisol and other glucocorticoids from the adrenal gland. However, its role in the brain independent of the hypothalamus–pituitary–adrenal axis has been firmly established. Consistent with its role as a neurotransmitter mediating complex repertoires, CNS administration of CRF mimics many of the behaviors and autonomic responses seen with physiological stress.

There are multiple experimental paradigms implicating the central CRF system as the prime mediator of the acute and prolonged stress response. Rodents administered CRF directly into the CNS

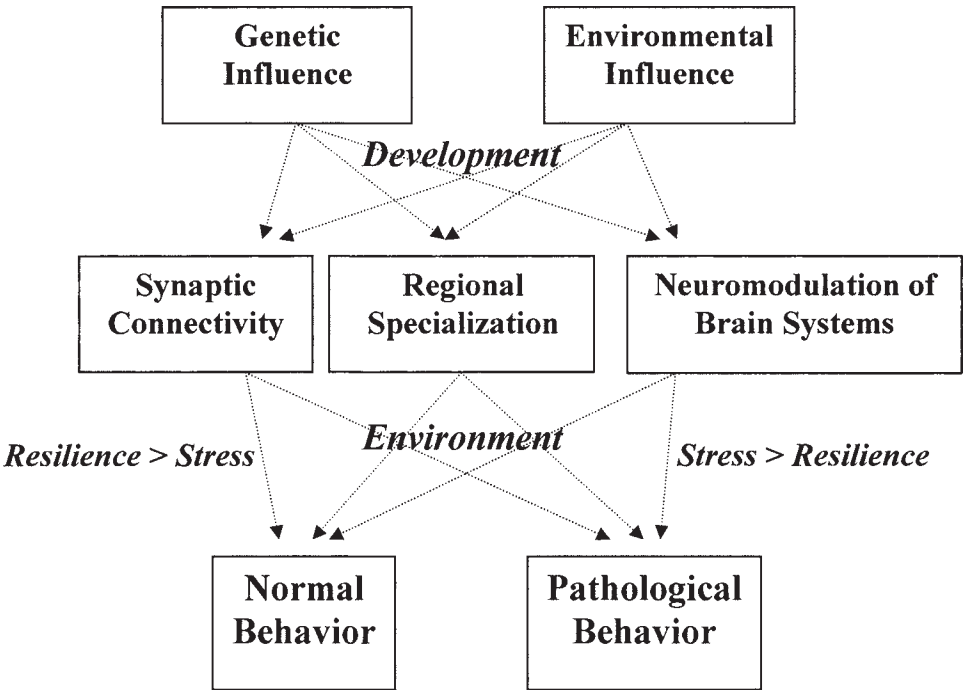

Figure 123-4 Interaction of genetic and environmental influences on behavior. Schematic diagram illustrating the interaction through development of genetic and environmental influences on different levels of brain organization. Interplay between developmental genetic programs and environmental insults leads to differential effects on synaptic connectivity, regional neural systems, and brain-wide neuromodulation. Normal behavior results when the genetic and environmental influences lead to resilience outweighing stress effects on brain and behavior. Alternatively, when either too much stress or too little resilience interact pathological behavior arises in the form of psychiatric syndromes.

show decreased reproductive behaviors, altered sleep, increased grooming, increased signs of despair, increased neophobia, and altered appetite, all of which mimic the behavioral stress response. Furthermore, rodents raised with early life-stress hypersecrete CRF from the hypothalamus and amygdala, both during the stress and later as adults. The maternal separation paradigm previously described leads to offspring with enhanced levels of apparent anxiety and depressive symptoms. Such animals have enhanced levels of CRF mRNA expression as well as enhanced release of CRF. Early untoward life events associated with development of depression and anxiety in adulthood give rise to long-lasting changes in CRF neurons, thus, increasing individual vulnerability for affective and anxiety disorders.

INFLUENCE OF GENETICS, DEVELOPMENT, AND ENVIRONMENT TO CREATE INDIVIDUAL BEHAVIOR

Considerable effort has been expended to develop a valid animal model of depression. Virtually all of the extant models have focused on either developmental (maternal separation) or environmental (learned helplessness) chronic unpredictable stress to generate a depressed phenotype. Additional animal models have been created through the use of mice with transgenic DNA insertion or homologous recombination (knockouts). One of the most impressive models is the serotonin receptor ($5HT_{1A}$) knockout. Mice lacking this receptor exhibit anxiety and fear behavior in several behavioral paradigms. Elegant molecular biology techniques have been used to "rescue" the phenotype of these knockout animals. In a $5HT_{1A}$ mutant mouse background strain, a tissue specific promoter is used to replace the $5HT_{1A}$ gene within neurons of the hippocampus, amygdala, and forebrain, but specifically not the raphe nuclei in which serotonin is produced. This limited expression is sufficient to normalize the behavioral phenotype of $5HT_{1A}$ knockout mice. This suggests that it is the $5HT_{1A}$ gene in postsynaptic neurons within these target areas that contributes to the development of anxiety-like behavior, and not its role in auto-feedback on the raphe neurons themselves. Finally, use of a conditional gene that can be replaced for a limited period of time has shown that the replacement is only necessary during development. If the $5HT_{1A}$ gene is replaced only during the first month of life, but is absent again in adulthood, the animal shows normal levels of anxiety-like behavior as an adult. However, if it is replaced only in adulthood and not earlier during development, the behavioral phenotype is not restored. These data reveal how a specific interaction between a gene and development can lead to establishing normal and abnormal adult anxiety-like behavior in the context of stressful environments.

PSYCHOPATHOLOGY RESULTS FROM INTERACTION OF GENETIC RISK FACTORS WITH ENVIRONMENTAL INSULTS

Neither genetics nor environmental influences alone lead to behavior. Rather, both normal and abnormal states of behavior result from an intricate interaction in which environmental influences are limited by genetic programs to produce a functioning brain and its resultant behavior. Figure 123-4 illustrates schematically how these different influences combine to produce behavior, both normal and pathological.

The relative contributions of genetics, development, and stress contributing to illness are becoming understood in terms of brain biology. Temperamental influences clearly place "reactive" infants

and behaviorally inhibited children at higher later risk for anxiety and affective disorders. Substantial data is accumulating supporting the preeminent role of early adverse experience in increasing vulnerability for mood and anxiety disorders. The complex interaction of environment with the 5HTT gene, specifically this "l" vs "s" promoter polymorphism discussed above, affects the risk of depression. This polymorphism moderated the influence of stressful life events on depression. Individuals with one or two copies of the short allele of the 5HTT exhibited more depressive symptoms than did those homozygous for the long allele. However, this difference in depression symptomatology was only seen in individuals who reported early stressful life events. Furthermore, there was a clear interaction between number of stressful life events and depressive symptoms in the "s" allele carriers, but not in the "l" allele homozygotes.

Through molecular mechanisms that affect the way neurons communicate with each other, the way region-specific genes are regulated, and the way in which brain-wide neuromodulation occur, genetic constraints interact with environmental influences to produce behavior, both normal and abnormal. Abnormalities in behavior lead to the symptom clusters that occur in psychiatric disease. For example, in clinical depression, patients are generally hypersensitive to stress and fear states. They are more likely to experience anxiety, defeat, and anger as well as having decreased attention and concentration. They are unable to experience pleasure and have very low self esteem. They also show neurovegetative signs of altered appetite, libido, and energy. The paragraph below outlines how these symptom clusters can arise from the impaired neural pathways that result during depression.

Genetic predispositions and environmental influences affect the neural circuits that mediate stress responsiveness and modulation of emotion. The alterations in midbrain neuromodulatory systems likely contribute to these increased vulnerabilities. With sufficient stress, these systems are dysregulated, leading to increased stress and fear responsiveness. Hypersensitive limbic pathways lead to experiences of defeat, anxiety, anger, negative mood, and aggression. Abnormal cortical regulation through altered plasticity mechanisms and abnormal neuromodulation likely underlies impaired concentration and memory, worry, and inability to control negative thoughts. Hypothalamic abnormalities likely contribute to altered appetite, libido, energy, and autonomic symptoms. Brainstem and thalamic abnormalities likely contribute to altered sleep and arousal states.

Treatment of depression and anxiety with antidepressants leads to alterations in these and related abnormal circuits, not necessarily resulting in normalization of the circuitry, but with amelioration in the symptoms. It is likely that there are many different pathways for the brain to become dysregulated leading to a syndrome of depression, and that different combinations of genetic and environmental influences can interact. Treatment may now appear similar for all types of depressive syndromes, but new data suggest that subtypes of depression indeed respond differentially to different treatments, for example, psychotherapy vs pharmacotherapy.

CHALLENGES FOR THE FUTURE

A primary goal of psychiatry is to continue to uncover the molecular mechanisms underlying mental health diseases. As these mechanisms are further elucidated, they will provide further understanding of the role of both environment and genetics in the molecular underpinnings of psychiatry. More importantly with such an understanding, more will be possible in prevention of environmental insults as well as in the availability of novel molecular targets for drug development.

Further understanding of genetic contributions to psychiatric illness will also provide powerful tools for evaluating an individual's genetic risk. Understanding risk may help physicians counsel patients to help them reduce subsequent environmental insults. Further understanding of genetic and environmental molecular mechanisms may help guide pharmacotherapy and psychotherapy in determining optimal individualized treatment.

Finally for the more severe psychiatric illnesses such as schizophrenia and bipolar disorder, knowing significant risk might be helpful for prevention through both pharmacological and psychotherapeutic means. Additionally, such awareness of risk would assist in initial diagnosis, helping to significantly curb illness onset and severity when symptoms first appear.

A much greater understanding of brain function may allow for the eventual combined understanding of genetic and environmental influences on molecules, cells, circuits, and systems within the brain. Through such advances in understanding, more powerful models of psychiatric disease are possible, with the effect of eventually developing psychopharmacological agents that target only the specific molecular "lesions" affected in the individual patient. As the brain is an organ for learning, there may be new approaches using combined pharmacotherapy with psychotherapy, in which the pharmacological approach is aimed specifically at enhancing the learning and utilization of the psychotherapy tools. Through such approaches, ways may be found to use the molecules of pharmacology to target the molecular deficits and new "environmental" experiences that allow the brain to correct itself in individual-specific ways.

124 The Complex Genetics of Psychiatric Disorders

Ming T. Tsuang, Stephen J. Glatt, and Stephen V. Faraone

SUMMARY

Unlike many single-gene neurological disorders such as Huntington's disease, neurofibromatosis, and Rett syndrome, most psychiatric illnesses are etiologically complex. It is this complexity that stands as the major obstacle hindering risk-gene identification in psychiatry, and all of the diagnostic, therapeutic, and preventive advances that such discoveries might engender. Linkage and association analyses will probably be able to resolve some of the genetic complexity of many psychiatric conditions; but it is also likely that emerging disciplines, such as systems biology and functional genomics, will inform traditional genomic methods to hasten the compilation of a full catalog of susceptibility genes for psychiatric illness.

Key Words: Heterogeneity; oligogenic; polygenic; pooling; psychiatric disorders; splitting.

INTRODUCTION

The methods of genetic epidemiology, particularly twin and adoption studies, have unequivocally demonstrated that most if not all psychiatric disorders have some genetic basis. However, the relative contribution of genetic and nongenetic factors to the development of each of these illnesses varies widely. For conditions such as autism, bipolar disorder, and schizophrenia, genes are responsible for the majority of total illness susceptibility, whereas the genetic contribution to risk for other conditions such as social phobia and several personality disorders is low (Table 124-1). For the more genetically driven psychiatric illnesses, it was anticipated that the unraveling of the human genome would facilitate the determination of their genetic underpinnings, but this idea is largely unrealized. Few specific genetic risk factors for even the most heritable and most commonly studied psychiatric conditions (e.g., autism, bipolar disorder, and schizophrenia) have been identified; even fewer have been validated in independent samples, and none have been evaluated prospectively.

Although much more genetic and genomic analysis of psychiatric illnesses remains to be done, it is apparent at this relatively early stage of inquiry that traditional gene-finding strategies will not easily yield the goal of psychiatric genetic inquiry—a specific genetic etiology for a given illness. If the emergent harnessing of the human genome is expected to produce dividends for the diagnosis, treatment, and ultimately prevention of psychiatric disorders, understanding of these illnesses must grow, along with the scope of genetic epidemiological methods used. Unlike many single-gene neurological disorders such as Huntington's disease, neurofibromatosis, and Rett syndrome, most psychiatric illnesses are etiologically complex. It is this complexity that stands as the major obstacle hindering risk-gene identification in psychiatry, and all of the diagnostic, therapeutic, and preventive advances that such discoveries might engender.

THE GENETIC COMPLEXITY OF PSYCHIATRIC DISORDERS

The main factors contributing to the complexity of psychiatric disorders can be broadly divided into those that relate to the small size and great quantity of risk factors for these conditions, and those that produce various types of heterogeneity. Of note, both classes of complicating factors are problematic because of their effects on inferential power. For example, regarding the first complicating factor, genetic epidemiological methods and molecular genetic techniques consistently demonstrate that psychiatric illnesses are not caused by single genes that always precipitate illness in all individuals possessing the gene. Rather, these procedures typically yield evidence for multiple (sometimes many) susceptibility genes, each of which may have a relatively restricted effect on the total risk for a given disease. Regarding the second factor, the complexity introduced by heterogeneity can come from the nonuniformity of the phenotype, whereby the same genes can produce numerous distinct clinical pictures, or from the nonuniformity of the etiological factors, which can produce different paths to the same disease.

Psychiatric geneticists now appreciate that even the most advanced molecular and statistical genetic techniques will not have optimal power unless each of these complicating factors—multiple risk genes with small effects, and heterogeneity—are adequately addressed in research studies even before the first piece of data is collected. Common strategies for overcoming these obstacles to risk-gene discovery are discussed later, along with the negative consequences that may be realized if these steps are not taken.

Table 124-1
Heritability and Status of Association Testing of Various Psychiatric Disorders

Psychiatric disorder	*Heritability (%)*	*Allelic association studies (n)*
Autism	93	56
Tourette's disorder	90	27
Schizoaffective disorder	85	34
Bipolar disorder	84	287

THE COMPLEX, MULTIFACTORIAL POLYGENIC ETIOLOGIES OF PSYCHIATRIC DISORDERS The greatest contributions of the molecular genetic revolution to medicine have been in the identification of individual genes that are solely responsible for the development of hundreds of devastating diseases, including cystic fibrosis, phenylketonuria, thalassemias, myotonic dystrophy, fragile-X syndrome, and some forms of breast cancer, in addition to the neurological disorders introduced previously. The practical impact of these discoveries is realized on a daily basis in the forms of increased diagnostic certainty for these diseases, targeted treatments at the molecular level, prenatal diagnoses, and personal and familial risk assessments. These are also the ambitious goals of those who study psychiatric conditions, but these objectives can only be reached after the elusive genes underlying these conditions are finally isolated, and this task has proven far more difficult than initially anticipated.

Before modern molecular genetic techniques made genome-wide DNA analysis possible, the mathematical analysis of illness transmission through pedigrees was used to test hypotheses about the number and mode of inheritance of genes underlying these disorders. These mathematical techniques, collectively known as segregation analysis, generally did not support single-gene inheritance models of autism, Tourette's disorder, bipolar disorder, schizophrenia, schizoaffective disorder, attention-deficit/hyperactivity disorder, or alcohol abuse, among other psychiatric illnesses. Instead, the etiologies of these disorders were more often found to be consistent with oligogenic (caused by a few genes) or polygenic (caused by many genes) inheritance patterns; however, the precise number of risk genes estimated to be responsible for each disorder typically varied across studies. Today, most cases of psychiatric illness are presumed to have multifactorial polygenic etiologies, in which numerous genetic and environmental risk factors interact; however, a small fraction of families exhibit evidence for rare single-gene forms of some psychiatric illnesses, including bipolar disorder, major depression, obsessive–compulsive disorder, dyslexia, and panic disorder.

Because the previously mentioned psychiatric disorders were known from twin studies to have such a strong genetic component (Table 124-1), the technological advances in molecular genetics made during the 1970s and 1980s ushered in a period of great optimism in the possibility of finally localizing and identifying their causative genes. Initially, the chromosomal loci of the genes for autism, bipolar disorder, and schizophrenia were sought by methods of linkage analysis, which correlate phenotypic and genetic similarity among family members to allow the identification of broad chromosomal regions that may be involved in the disease. Evidence suggesting genetic linkage to these and other disorders soon followed, generating a great deal of excitement that the genes underlying these disorders were finally within reach. However, as attempts were made to replicate these findings, a disturbing pattern emerged: very few of the initially implicated chromosomal regions showed evidence of linkage with these diseases in other samples, although loci previously determined to be unlinked showed evidence for linkage. This problem of nonreplication increased as more reports emerged, suggesting the possibility that these studies were actually underpowered to produce similar patterns of results if these disorders were, in fact, polygenic. For example, simulated data has been used to show that typically designed linkage studies have adequate power to detect any one out of a number of linked loci, but low power to detect a particular target locus (as might be the goal of a replication study).

The shortcomings of linkage analysis have been demonstrated through the use of simulated data; between 185 and 4260 families (depending on the frequency of the disease allele) would be needed to detect a locus containing a gene with a relative risk of 4

by linkage analysis; yet the vast majority of linkage studies of psychiatric disorders have sampled far fewer than 200 families each. Hence at best, such studies may be detecting those chromosomal loci harboring the genes with the greatest effects on risk but, presumably, the numerous genes that confer less than a fourfold increase in disease risk would go undetected. In fact, to detect linkage at a chromosomal locus harboring a gene that confers a relative risk of 1.5 for a given disease (i.e., the gene increases risk by 50%), the number of families needed for analysis becomes unreasonably large; the number is so excessive (between approx 18,000 and 4.6 million families, depending on the disease-allele frequency) that such a quantity of eligible pedigrees would likely never be attainable for even the most common psychiatric conditions. Thus, it would not be expected that the loci of genes that carry a relative risk of 1.5 would ever be implicated in individual linkage studies of even several hundred families.

For this reason, allelic association analysis, which directly tests for linkage disequilibrium between a genetic marker and a disease gene, has been advanced by some as a more powerful gene-finding strategy for complex disorders with presumed polygenic etiologies. For example, a gene carrying a relative risk of 1.5 for a given disorder would be detectable by allelic association testing in as few as 949 or as many as 19,320 parent–child trios (depending on the proportion of heterozygous parents in the sample). Even in the worst-case scenario, this sample size compares favorably with the more than 4.6 million families that would be needed to detect this locus by linkage analysis, especially when considering the relative ease of ascertaining trios with one affected offspring for association analysis vs ascertaining families with affected sibling-pairs for linkage analysis.

Psychiatric geneticists have tried to leverage the greater power and efficiency of allelic association analysis to find genes for many psychiatric illnesses, including each of those disorders that had previously been examined for genome-wide linkage and many other disorders that had not yet been the subject of linkage analysis. The results of more than 2600 allelic association studies of psychiatric disorders have been published (Table 124-1), and many significant associations have been noted. However, as with linkage analyses, allelic association analyses also suffer from a bewildering propensity for nonreplication. This phenomenon is especially frequent for complex diseases, including psychiatric disorders. In some instances, nonreplication of a documented association becomes so frequent that the initial finding of association becomes rightly seen as a type-I inferential error. Other apparent nonreplications are simply resulting from random sampling errors around a small but real effect. Thus, although one study may detect an association that is slightly larger (and more significant) than the true association, another study will detect a smaller (and nonsignificant) effect. The true nature and magnitude of such associations may be eventually clarified after several replication studies have been conducted; but for some associations, even numerous replication efforts fail to clarify the issue. This variability illustrates the need for strategies that maximize the power to detect genes with very small effects on risk, even within the relatively powerful association analysis paradigm.

Thus, some of the great etiological complexity of psychiatric disorders is a function of the large number and small magnitude of their underlying genetic risk factors. The shortcomings of linkage and association analyses for identifying the risk genes for these disorders (or even their general chromosomal location) are most visible as a chronic failure to replicate even the strongest evidence for the involvement of particular genes or loci. This, however, does not necessarily indicate that these methods are somehow faulty and will never be used to successfully locate the risk genes for psychiatric disorders. On the contrary, these methods may ultimately prove to be the best possible means of accomplishing this goal. However, there clearly is room to improve on these methods, and to implement them in more powerful ways in order to hasten the discovery of the risk genes for this group of complex disorders.

THE HETEROGENEITY OF PSYCHIATRIC DISORDERS In addition to the fact that most psychiatric disorders have multifactorial polygenic etiologies with multiple underlying risk genes of small effect, the heterogeneity of these disorders contributes to the difficulties experienced in isolating their risk genes. Two main types of heterogeneity can be delineated: clinical heterogeneity and causal heterogeneity. Clinical heterogeneity exists in which more than one condition can be brought about by the same cause, although causal heterogeneity exists in which two or more causes can independently lead to the same condition. Through different means, both forms of heterogeneity serve to obscure the effects of risk genes, delaying and sometimes even preventing their identification.

Clinical heterogeneity is a problem for psychiatric genetics because it complicates the proper identification and ascertainment of individuals who may be carrying the same risk genes. For example, in a given family through which several risk genes for schizophrenia are segregating, the individual family members may present with a wide range of illness, from full schizophrenia through none at all. Between these extremes, other family members may display varying degrees of illness, receiving diagnoses of conditions that appear to be more or less related to schizophrenia. For example, some individuals may be diagnosed with schizoaffective disorder, whereas others receive a diagnosis of schizotypal personality disorder, and still others do not qualify for any commonly accepted diagnosis but still show subtle signs of disruption in particular domains of social and neuropsychological functioning. These intermediate conditions, or schizophrenia-spectrum conditions, are more common among the biological relatives of schizophrenic patients than among the relatives of control subjects or in the general population, suggesting that they share some genetic basis with schizophrenia. It is also common for schizophrenia and other psychiatric conditions to show some degree of discordance between monozygotic twins, who share 100% of the same genes. Findings such as these evoke a critical question: Why do related individuals who share the same genetic risk factors (to a greater or lesser degree, depending on the nature of their relationship) have different psychiatric outcomes?

To answer this question, the multifactorial polygenic nature of psychiatric disorders must be considered; that is, even the most heritable of these conditions have some environmental underpinnings. Thus, in families in which risk genes for a highly genetically based disorder are shared, the resulting differences in the degree of psychiatric impairment among individual family members are governed by environmental factors, in which the most severely affected members may be those who, in addition to possessing the risk genes, also were subjected to unfavorable environmental circumstances. The combination of enough detrimental genetic and environmental risk factors may ultimately cause an individual's total susceptibility to surpass some threshold level, beyond which the full disorder (in this case, schizophrenia) would be expressed. Conversely, psychiatrically well members of families with a high genetic propensity toward illness may not have experienced any such environmental circumstances or, indeed,

may have been exposed to protective environmental factors. Those family members expressing varying degrees of schizophrenia-spectrum deficit may have varying combinations of these risk factors, some individuals with more genetic risk and others with more environmental risk. Such a "multifactorial threshold" model fits familial patterns of illness for many complex psychiatric disorders, including schizophrenia.

Thus, the possession of specific risk genes for a complex illness (or a specific environmental factor, for that matter) does not place an individual at absolute risk for that disorder; this is the essence of complex diseases. Possessing such risk factors may place an individual along a continuum of risk for that illness, which may or may not correspond to the actual presentation of some or all of the features of the illness. This information is reassuring to those individuals from affected families, as they can recognize that their genetic susceptibility to disease is not absolute and can be modified by environmental variables. However, such phenomena make the identification of risk genes much more difficult than would be the case if every individual with the same genes exhibited the same phenotype. Thus, in linkage and association studies, the incomplete penetrance of risk genes (i.e., their less-than-absolute causation of disease) will lead some subjects who possess those risk genes to be labeled as well. Consequently, the possession of those particular risk genes in well individuals will cause the evidence for the involvement of those genes in the disease to appear weaker.

The other dimension of heterogeneity—causal heterogeneity—is probably common in psychiatric disorders. If these disorders are caused by the interaction of many genetic and environmental factors, it is likely that no single factor is either necessary or sufficient to produce disease. If each genetic and environmental risk factor independently increases risk by a small amount, it may be the total liability that is achieved (rather than the identity of its constituent factors) that determines illness. For example, if there were 10 risk factors that predisposed to schizophrenia-spectrum illness (five genes and five environmental experiences), but only four of these (in any combination) were needed to reach the threshold for full schizophrenia, there would be 210 different routes to schizophrenia. Some of these etiological paths would overlap almost entirely, some only partially, and others not at all. In addition, some of these paths to schizophrenia would be entirely genetically determined, whereas others would be produced by a combination of genes and environmental factors. Other cases (called phenocopies) might be caused solely by environmental factors. Phenocopies are particularly problematic for genetic studies because they will be counted as affected individuals but will show no evidence implicating the risk genes that underlie the true genetic or partially genetic forms of the disease, with a net effect of reducing the strength of genetic linkage or association detected in the group of affected individuals.

Alzheimer's disease is a prototypical example of a psychiatric illness with heterogeneous causation. For example, mutations in any one of three different genes (amyloid-β precursor protein, presenilin-1, or presenilin-2) will almost invariably cause Alzheimer's disease, independent of the presence of other risk genes or deleterious environmental circumstances. To add to this complexity, the familial, early-onset forms of the disorder caused by mutations in any of these genes only account for a small fraction of the total cases of Alzheimer's disease. In fact, the majority of cases are probably attributable to an unknown combination of genetic and environmental factors, although several specific risk genes are becoming recognized, including α-2-macroglobulin, angiotensin I converting enzyme 1, and apolipoprotein E.

The presence of multiple genetic paths to psychiatric illness will have clear detrimental effects on the power of positional cloning studies. For example, the genetic signals obtained in an unfocussed search for genetic risk factors, as typically conducted by linkage analysis, might go unnoted unless specific allowances for heterogeneity are built into the underlying statistical models of inheritance. Furthermore, the genetic signals obtained from a focused examination of a candidate gene, as in an allelic association study, could be reduced or potentially eliminated if, for example, the cause of the illness in the sampled population is a gene or genes other than the candidate gene being investigated.

UNRAVELLING THE COMPLEX GENETICS OF PSYCHIATRIC DISORDERS

It is clear that the multifactorial polygenic etiologies and heterogeneity of psychiatric disorders obscure the discovery of their underlying genetic bases. The multifactorial polygenic nature of these diseases dictates that the "signals" obtained in linkage and association studies will be numerous and of very low intensity, although the heterogeneity of these disorders increases the "noise" against which these already-faint signals must be detected. Some of the most effective ways of combating these complexities are through the maximization of power, both by increasing sample size and by studying homogeneous groups of affected individuals. To identify the numerous genes with small effects on the risk of psychiatric illness, various data-pooling strategies (collectively referred to as "pooling") are particularly effective. However, to overcome the obstacles introduced by heterogeneity, delineating and studying smaller, more homogeneous subgroups of affected individuals (called "splitting") may have the greatest beneficial effects on power. When used in tandem, the practices of pooling and splitting yield maximal power in genetic studies.

POOLING STRATEGIES FOR RESOLVING THE MULTIFACTORIAL POLYGENIC NATURE OF PSYCHIATRIC ILLNESSES As previously illustrated, statistical simulations indicate that the power of typically designed linkage and association studies is woefully inadequate for detecting genes with very small effects on disease risk (e.g., relative risk = 1.5). Unfortunately, the genes underlying most psychiatric disorders are likely to have relative risks on approximately this order of magnitude. Thus, one of the greatest challenges to the successful implementation of these methods is their low power, limited by the typically low sample size of individual studies. Large collaborative studies and meta-analyses of existing datasets offer opportunities to overcome this obstacle.

Indeed, the psychiatric linkage analysis literature has already been clarified by meta-analyses of linkage studies for schizophrenia, bipolar disorder, and autism, which have revealed strong evidence for multiple linked loci for each disorder. For example, individual linkage analyses of schizophrenia have found at least suggestive (if not significant) evidence for linkage with the disease in no less than 16 distinct chromosomal regions (Fig 124-1). However, two different meta-analytic pooling techniques have produced evidence for only three strongly linked loci, one of which (centromeric region of chromosome 2p) was in a location not strongly implicated in any of the individual linkage analyses. The meta-analyses of bipolar disorder and autism linkage analysis

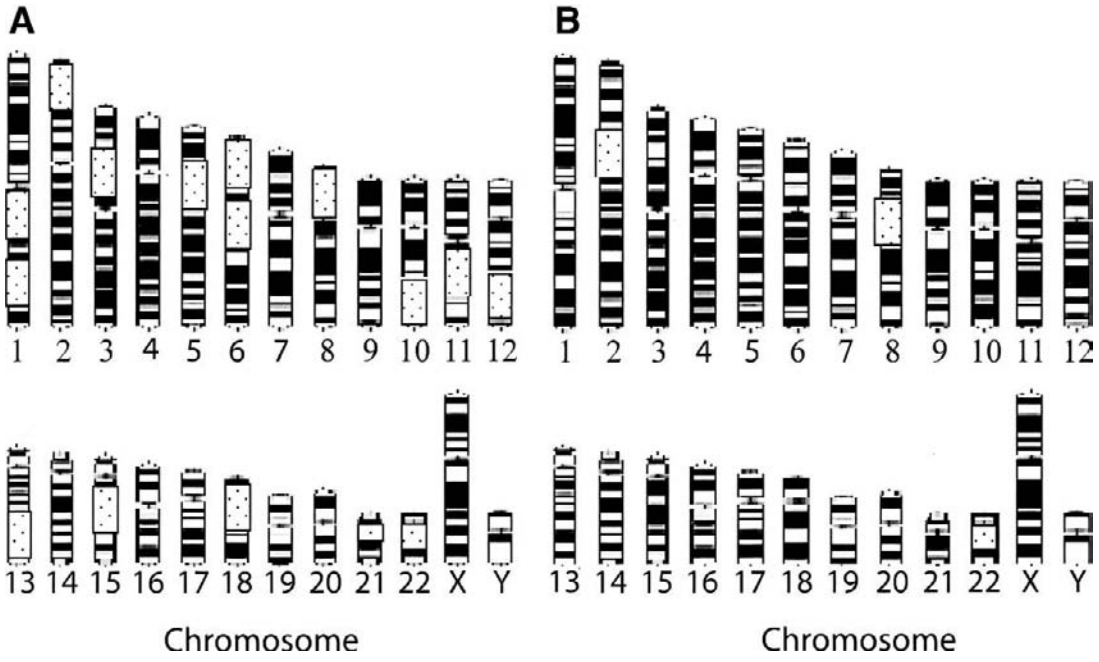

Figure 124-1 Chromosomal loci showing at least suggestive evidence for linkage (⋰⋱) with schizophrenia in at least one individual linkage study **(A)** and in both meta-analyses of linkage studies **(B)**.

datasets have been equally enlightening, and suggest clear targets for further analysis by both linkage and association methods.

Although these meta-analyses provide useful directions for future positional cloning efforts, they are unlikely to have detected all the genes involved in these disorders. Linkage methods and the resulting meta-analyses of their data may detect loci that harbor genes with the largest effects on disease susceptibility, but other disease loci with smaller yet meaningful effects on risk will elude detection. For example, recalling that between 185 and 4260 families would be needed to detect a locus containing a gene with a relative risk of 4.0 by linkage analysis, it is reasonable to presume that these meta-analyses (which have pooled data from 700 or fewer families) did not detect all susceptibility loci for these diseases. Again, the number of families needed to detect a chromosomal locus harboring a gene with a relative risk of 1.5 (between 18,000 and 4.6 million families) is not even approached in these meta-analyses.

The tangible impact of this "power failure" can be seen in a concrete example from the psychiatric genetic literature. For example, not a single linkage analysis for schizophrenia, nor either of the meta-analyses of these linkage studies, identified chromosome 3q as a strong candidate locus for the disease; yet, the gene that codes for dopamine receptor D3 (DRD3, chromosome 3q13.3) carries a relative risk for schizophrenia of 1.3 or less, an effect which has been repeatedly demonstrated by allelic association, and confirmed in separate meta-analyses of these association studies. This finding is a direct result of the greater power of association studies relative to linkage studies and, consequently, the greater power of meta-analyses of association studies as well. Again, recalling that a gene conferring a relative risk of 1.5 can be detected in as few 949 trios by allelic association (as opposed to 18,000 or more families for linkage analysis), many associations with psychiatric disorders have already been tested often enough to yield pooled samples with enough power to detect these small but important associations; the meta-analyses of the association between DRD3 and schizophrenia, each with pooled sample sizes of greater than 2600 patients and 2500 control subjects, again provides a compelling example. Thus, it appears that one of the simplest ways to overcome the fact that most psychiatric disorders have numerous risk genes with small effects is to maximize inferential power by increasing sample size. However, such maximization of power, either through collaborative studies or meta-analysis, is not the only option for improving risk-gene detection methods when individual genetic effects are small. In fact, the ability to identify risk genes with small effects can be enhanced as a byproduct of implementing procedures that also overcome the difficulties introduced by clinical and causal heterogeneity.

SPLITTING STRATEGIES FOR OVERCOMING THE HETEROGENEITY OF PSYCHIATRIC DISORDERS Clinical and causal heterogeneity are detrimental to gene-finding efforts for complex diseases to the degree that they obscure detection of the effects of individual risk genes by increasing the "noise" surrounding them. In the case of clinical heterogeneity, the improper or incomplete specification of the affected phenotype may cause misclassification of subjects, allowing some overlap of risk genes to be detected in affected and unaffected individuals in which no such overlap truly occurs. Similarly, the apparent effects of genes are reduced in the presence of causal heterogeneity: because several nonoverlapping or partially overlapping genetic etiologies may exist in a population, a given genetic risk factor may not be present in a large proportion (perhaps even the majority) of individuals with a disorder.

In overcoming these difficulties, simply increasing sample sizes by pooling may not be enough. Instead, splitting techniques (e.g., cluster analysis, recursive partitioning, and classification and regression trees) may yield greater gains in power through the delineation of smaller (rather than larger) groups of subjects. The objective of this splitting strategy is to delineate homogeneous

subgroups of a disorder that are clinically distinct from each other, under the assumption that clinical homogeneity within groups reflects (at least to some degree) underlying etiological or causal homogeneity. Within such causally homogeneous subgroups, the genetic risk should be more uniform and, thus, the effects of risk genes will be more pronounced and easily detected. In essence, this strategy is designed to maximize the observable genetic signal within a given subgroup although minimizing the noise that might typically arise from jointly examining groups of individuals whose seemingly identical conditions are caused by partially or entirely distinct etiologies.

In practice, splitting techniques are most effective when used in conjunction with (not in opposition to) pooling techniques. The maximization of sample size through pooling affords greater power and reliability to the splitting methods that will be subsequently employed. In addition, pooling before splitting will ensure that delineated subgroups have large enough sample sizes to be powerful samples on their own. The pooling-then-splitting method can be applied in single studies, given that they have large enough samples; however, power will be greatest when data can be directly pooled from multiple samples. These methods can also be applied to published studies through the use of meta-analytic methods, whereby studies can be divided into subgroups based on some design feature, or heterogeneity among the pooled studies can be explained by regressing the size of the genetic effect obtained in each study against key characteristics of those studies, such as sample ethnicity or age-at-onset in the patient group.

THE FUTURE OF GENE-FINDING EFFORTS FOR PSYCHIATRIC DISORDERS

It is likely that even if the pooling and splitting strategies advocated above are implemented, other methods will be needed to comprehensively delineate the genetic contributions to psychiatric disorders. Methods in use in other fields of medical research, such as immunology, cell biology, and physiology, may be used to meaningfully contribute to the search; however, it is also likely that new and developing methods will lead to gene discovery. A brief review of some of these promising techniques clearly shows that emerging methods of genomic and postgenomic analysis emphasize high throughput and comprehensiveness, allowing research to remain hypothesis-driven whereas simultaneously employing broader, more inclusive standards in identifying potential "candidate" genes for study.

MINING THE TRANSCRIPTOME, THE PROTEOME, AND BEYOND As twin and adoption studies clearly show, most psychiatric illnesses have a genetic component, i.e., at least some of the susceptibility to these illnesses is passed vertically through generations by the inheritance of particular DNA sequence variations. For this reason, the search for risk genes for these disorders naturally began with the study of DNA sequence variation in multiply affected pedigrees by linkage analysis and in nuclear families and individuals by association analysis. However, the analysis of DNA sequence variations does not tap all of the complexity of the human genome, and cannot account for heritable variations in gene expression that may also play a critical role in disease development. These so-called epigenetic phenomena may be better understood by analyzing the RNA transcripts and proteins specified by genes.

DNA sequence variations dictate which RNA transcripts and, ultimately, which proteins can be produced by cells. However, other factors govern these processes as well, and the rate and location of transcript and protein production may also be influenced by extragenomic factors. Transcripts and proteins can be viewed as more proximal than genes to the disease state, which has made them logical targets for study in postgenomic analyses. Microarray technologies, in which the expression levels of thousands of genes can be simultaneously examined, are now being used to assess altered patterns of gene regulation in various psychiatric illnesses, including autism, major depression, schizophrenia, and bipolar disorder.

Microarray analyses are valuable because the expression of many genes can be examined simultaneously. Unfortunately, because of alternate splicing of transcripts and post-translational modifications in proteins, the number of transcripts and proteins available for study is far greater than the number of genes in the genome. Thus, these procedures, although potentially powerful, further illustrate the potential genomic and extragenomic complexity that may be encountered in the comprehensive analysis of psychiatric disorders at the molecular level.

MULTI-INFORMANT ANALYSIS No existing or forthcoming genetic analysis method is likely to solve all of the problems encountered while hunting the genes for mental illnesses. More likely, as when studying other difficult problems in science, a combination of approaches will prove the most useful in understanding psychiatric phenomena in all of their complexity. Researchers are becoming increasingly aware that individual methods employed at a single level of analysis cannot hope to capture the essence of these disorders, which most likely involves changes at many levels of numerous biological systems. Also, adopting an interdisciplinary perspective allows optimal utilization of valuable research resources; the richness of samples collected for genetic studies (from clinical data, to pedigree structures, to biological samples) is too great to be analyzed by a single method.

The field of psychiatric genetics is gravitating toward systems biological and integrative behavioral genomic approaches wherein multiple sources of information are used to build a preponderance of evidence implicating particular risk genes. Historically, the results of linkage analyses (i.e., linked chromosomal loci) have been used to inform the approach of association studies (i.e., targeted gene analysis within the linked region). This approach is now expanding to incorporate the findings from many other sources, including gene expression data and animal models of psychiatric illness. For example, in a typical microarray analysis of several thousand genes, many may appear to be differentially expressed in brain tissue from patients and control subjects. Although ideally each of these genes would then be investigated further for association with the disorder, practical constraints may hinder the implementation of this plan. Instead, the genomic location of each differentially expressed gene can be examined within the context of previous findings from linkage analyses of the disorder under investigation. Thus, those genes coding to a chromosomal region previously found linked to the illness can be given the highest priority for association analysis. If significance is observed in association analysis, the functional consequences of the responsible polymorphism can be investigated in transgenic or knockout animal models of the disease.

The advantages of employing such an integrative approach are clear. First, the inclusion of high-throughput methods in the chain of research will allow the identification of novel, previously unsuspected candidate genes for further analysis. Indeed, one of the major drawbacks of traditional allelic association testing is the paucity of objective criteria (aside from being in a linked chromosomal region)

for selecting candidate genes for study. In addition, relying solely on the results of linkage analysis to inform association testing is far from optimal because, as illustrated, linkage analysis is not very sensitive for detecting genes with very small effects on risk and, furthermore, association can sometimes occur in the absence of linkage. Second, the analysis of functional consequences of gene variation or epigenetic modification on transcription, translation, and behavior in animal models will provide some insights into the molecular mechanisms of these diseases. Finally, and perhaps most critically, a multidisciplinary and integrative approach will allow for the assessment and establishment of concurrent validity for genes putatively identified as risk factors by one method, thus, ensuring greater accuracy and reliability in classifying susceptibility genes for psychiatric disorders.

CONCLUSIONS

Psychiatric disorders are undeniably complex diseases. The etiology of all but a few of these conditions remain unknown, despite profound advances in the methods of psychiatric genetic epidemiology and statistical and molecular genetics. The tools of modern molecular genetic inquiry are useful in establishing the genetic bases of disorders caused exclusively by individual disease-genes; however, these tools may be suboptimal (at least as they are currently employed) for unraveling the multiple complex interactions of genetic and environmental risk factors that determine the liability toward most psychiatric illnesses. Yet, these methods should not be disregarded; rather, they should be utilized in a manner that maximizes their power. Two general methods to enhance the power of positional cloning methods such as linkage and allelic association analyses include pooling methods, in which raw data or individual studies are combined in collaborative studies or meta-analyses, and splitting methods, in which the genetic signal-to-noise ratio is maximized by delineating homogeneous subgroups of affected individuals that may have shared paths to disease. When these strategies are implemented jointly, linkage and association studies of complex psychiatric conditions will be maximally—if not optimally—powered to identify risk genes. However, until these disorders are more thoroughly investigated with positional cloning methods, it will remain unknown if maximal power equals adequate power for accomplishing these objectives. Linkage and association analyses will probably be able to resolve some of the genetic complexity of many psychiatric conditions; but it is also likely that emerging disciplines, such as systems biology and functional genomics, will inform traditional genomic methods to hasten the compilation of a full catalog of susceptibility genes for psychiatric illness.

125 Treating Depression

Antidepressant-Activated Signaling Pathways as a Source for Novel Drug Targets

MARCELO PÁEZ-PEREDA AND FLORIAN HOLSBOER

SUMMARY

Different hypotheses explain the etiology of depression. Each focuses on different biological processes that contribute to explain the clinical manifestation of depression and connect the regulation of mood to other biological processes such as the stress response and feeding behavior. Most likely, these different signaling pathways converge at a certain point to specifically control mood. This convergence point may control neurotransmission, in particular, long-term potentiation in the hippocampus. This opens the possibility that by dissecting pathways activated by antidepressants it would be possible to find new targets for novel drugs with a direct and specific mechanism of action, likely producing novel antidepressants with a higher potency, a faster action and fewer side effects.

Key Words: Antidepressant; calcium signaling; corticosteroid receptor; depression; monoamine.

INTRODUCTION

Current antidepressant treatments are efficacious. However, they work in only 70–80% of patients and often take often more than 5–8 wk to elicit patient response. Moreover, current treatment modalities are burdened by adverse effects and often produce only a partial remission, a risk factor for early relapse. To overcome these constraints, new molecular targets for antidepressant compounds are needed. Possible strategies to find these targets can be grouped into hypothesis-based and unbiased approaches. One possible strategy is to take advantage of the dissection of the signal transduction pathways that mediate the effects of the current antidepressants beyond the membrane receptor level. Alternative strategies are based on unbiased approaches that use gene expression profiling with DNA microarrays and proteomics or genome-wide genetic linkage.

There are examples that suggest that both approaches, hypothesis-based and unbiased, can be successful to find candidate targets. The pathway dissection of the monoamine-directed antidepressants led to the identification of the cAMP pathway as a key transduction mechanism. This led to the proposal that the use of phosphodiesterase (PDE) inhibitors would increase the effectiveness of monoamine therapies, which proved to be true. In another example, derived from the corticosteroid receptor hypothesis of depression, the use of glucocorticoid receptor (GR) antagonists may exert antidepressant effects. A pitfall of hypothesis-based approaches is that they suffer from the intrinsic limitations of the hypothesis on which they are based. It is not always straightforward to conclude that the function of a candidate target gene is involved in the control of mood or whether it is involved in related mechanisms that could produce side effects. Therefore, better drugs could be designed if the molecular pathways of the successful antidepressants are better known and new targets are identified. The use of unbiased approaches offers the possibility of overcoming these limitations. They also offer the theoretical possibility of finding targets that avoid side effects produced by known antidepressants. Unbiased approaches could be based on the identification of specific gene expression patterns using DNA microarrays or proteomics. As a proof of concept, an unbiased approach using gene expression profiling by microarrays identified components of the Wnt pathway as responsive to antidepressant treatment. Independent evidence proved that the mood stabilizer lithium chloride regulates the Wnt pathway. Yet another unbiased approach is the genome-wide scanning for DNA markers that could be associated with depression. There is evidence that risk factors for depression have genetic components. The use of genetic linkage studies may, therefore, identify these genes, providing more insight into the mechanisms that control mood, which could be used as novel targets to develop antidepressants. After the candidate gene identification process, further experimental proof of the specific involvement of these genes in the control of mood is required. Particularly in the case of unbiased approaches, the large amount of candidate targets poses the problem of prioritizing and selecting the best candidates for further studies.

This chapter explores different approaches to define the signal transduction pathways involved in antidepressant action and proposes criteria to prioritize candidate targets for antidepressant compounds.

THE MONOAMINE HYPOTHESIS

The first tricyclic antidepressants and monoamine oxidase inhibitors were discovered by serendipity. Both classes empirically showed improvement of symptoms in depressive patients. Later, the discovery of these compounds' biochemical mechanism of action led to the monoamine hypothesis of depression. Both types of antidepressants increase the levels of monoamines either by inhibiting their uptake by monoamine transporters (tricyclic antidepressants) or by inhibiting their inactivation (monoamine oxidase inhibitors). The development of selective serotonin or norepinephrine reuptake inhibitors has produced improved antidepressants, at least regarding their side-effect profiles. All of these compounds produce an increase in the extracellular levels of serotonin, norepinephrine, or dopamine. These monoamines, in turn, bind to their specific receptors at the plasma membrane and modulate the adenylate cyclase. Therefore, long-term antidepressant treatment results in the activation of the cAMP signal transduction pathway, mainly in the hippocampus and the forebrain (Fig. 125-1). This pathway further leads to the activation of protein kinase A (PKA) and the activation of the transcription factor cAMP-response element-binding protein (CREB). The involvement of this signal transduction pathway in chronic antidepressant action and its relevance for drug discovery is further emphasized by the fact that PDE inhibitors that increase cAMP levels, such as rolipram, increase the efficacy of antidepressants in clinical trials. CREB overexpression in the hippocampus driven by a viral vector produces antidepressant effects. However, the null mutation of CREB also produces antidepressant-like effects. Therefore, CREB activity in different brain areas might have opposite impacts on mood. One of the target genes of CREB is brain-derived neurotrophic factor (BDNF) (*see* Fig. 125-1). Antidepressant treatment results in the upregulation of BDNF, which is mediated by CREB. The administration of antidepressants together with the PDE inhibitor rolipram produces a strong increase in BDNF expression, supporting the involvement of the cAMP pathway in the effects of antidepressants on BDNF expression (*see* Fig. 125-1). BDNF itself has antidepressant actions when injected in high doses in the rat midbrain, suggesting that BDNF may mediate the antidepressant effects on mood. A proposed mechanism for BDNF antidepressant action involves its effects on neural plasticity and survival (*see* Fig. 125-1). BDNF also enhances long-term potentiation (LTP) and other forms of synaptic plasticity. The extrapolation of these results supports the view that BDNF could promote cell survival and neurogenesis in the hippocampus. Therefore, BDNF could hypothetically contribute to prevent or repair the neuronal damage induced by stress. However, definitive evidence that BDNF expression in the hippocampus is involved in antidepressant mechanisms is still missing. An alternative explanation for the antidepressant-like effects produced by BDNF in the hippocampus is that BDNF could increase the expression of tryptophan hydroxylase, which would increase serotonin levels and produce an indirect antidepressant effect (*see* Fig. 125-1).

BDNF knockout mice show an obese phenotype, suggesting that the induction of BDNF expression by antidepressants might be involved in the coordination between anxiety and appetite instead of the direct control of mood. Other proteins phosphorylated by PKA, independently from CREB and BDNF, could mediate the effects of antidepressants on mood. One of the PKA substrates activated in response to antidepressants is the dopamine and cAMP-regulated phosphoprotein 32 (DARPP-32) (*see* Fig. 125-1). Fluoxetine, serotonin, and serotonin receptor agonists cause phosphorylation of DARPP-32. At least some of the effects of DARPP-32 are mediated by protein phosphatase 1 (PP-1), which, in turn, regulates c-fos. This pathway is also reduced in DARPP-32-deficient mice but definite proof of this pathway's involvement in antidepressant effects is still needed.

THE CORTICOSTEROID RECEPTOR HYPOTHESIS

One of the main components of the stress response is the activation of the hypothalamic–pituitary–adrenal (HPA)-axis. Corticotropin-releasing hormone (CRH) is produced in the hypothalamus, and it stimulates the release of adrenocorticotropic hormone (ACTH) in the pituitary gland, which, in turn stimulates the production of glucocorticoids (Fig. 125-2). CRH production in response to stress is controlled by the hippocampus and the amygdala. An excessive activation of the HPA-axis is one of the main neuroendocrine alterations in patients with depression. CRH administration in different areas of the brain in rodents induces many of the symptoms observed in depressive patients. The ACTH increase in response to CRH injection and the suppression of cortisol in response to dexamethasone are absent in patients with depression. These responses follow the disease's clinical course and the improvement of these parameters precedes a successful response to antidepressant treatment. Therefore, CRH overproduction is thought to play a causative role in the development of depression. According to the Munich vulnerability study, the alterations in the HPA-axis also happen in healthy relatives of depressive patients. This strongly indicates that risk factors for depression have genetic components. The corticosteroid receptor hypothesis provides a mechanistic basis to explain the involvement of CRH in depression (*see* Fig. 125-2). Mineralocorticoid receptors (MRs) are localized in the hippocampus and control the inhibitory tone on hypothalamic CRH production by binding to endogenous glucocorticoids. CRH, in turn, also controls the levels

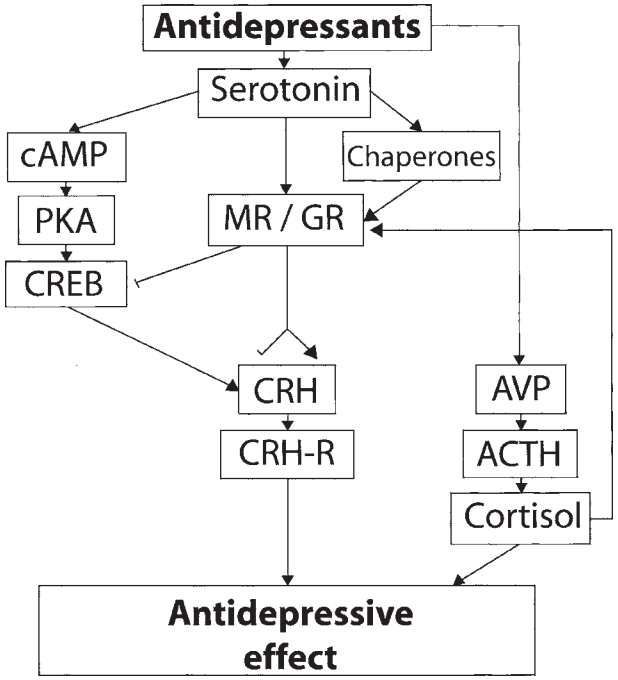

Figure 125-2 Diagram of the interactions between the corticosteroid receptors, the HPA-axis and the signaling pathways activated by antidepressants. ACTH, adrenocorticotropic hormone; CREB, cAMP-response element-binding protein; PKA, protein kinase A; MR/GR, mineralocorticoid receptor/glucocorticoid receptor; CRH, corticotrophin-releasing hormone; CRH-R, corticotrophin-releasing hormone receptor; AVP, arginine vasopressin; HPA, hypothalamic–pituitary–adrenal.

of corticosteroid receptors. Therefore, CRH overproduction in depressive patients could result from a dysfunction of MR inhibitory mechanism or from a dysfunction of corticosteroid receptors caused by CRH overproduction. In any case, the interaction between corticosteroid receptors and CRH plays a central part in the pathogenesis of depression. Further supporting evidence is the fact that long-term antidepressant treatment increases the mineralocorticoid and GR levels in the hippocampus and normalizes the levels of CRH production (*see* Fig. 125-2). Two possibilities that are not mutually exclusive may explain the antidepressant-induced reduction of CRH. Chemically enhanced activation of biogenic amine receptors (adrenergic and serotoninergic) through reuptake transporter inhibition results in desensitization followed by reduced PKA-mediated CREB phosphorylation and thus to decreased CRH gene activation via phospho-CREB action on the cAMP response element present in the CRH promoter. Concomitantly, antidepressants are able to increase GR function resulting in suppression of CRH gene expression. The administration of the MR antagonist, spironolactone, before antidepressant treatment with amitriptyline blocks the therapeutic response, indicating that MR function mediates antidepressant effects. A meta-analysis of antiglucocorticoid treatment of patients with major depression concluded that antidepressant effects happen in around 70% of the cases.

However, another study indicates that mifepristone, an antagonist of the GR, reduces symptoms in patients with psychotic depression. Therefore, the effects of glucocorticoids on depression seem to be dual. However, the effect of mifepristone might be limited to psychotic depression, in which many symptoms are explained by the high levels of cortisol, which is believed to activate dopaminergic neurotransmission.

CRH receptor1 (CRHR1) knockout mice show a clear low-anxiety phenotype. Based on this experimental and clinical evidence, the CRHR1 receptor has been proposed as a target for antidepressants (*see* Fig. 125-2). CRHR1 knockout mice are viable and show no pathological symptoms that could indicate that CRHR1 antagonists would produce significant side effects. In fact, CRHR1 antagonists have antidepressant effects on many experimental models of depression. An early open clinical trial with a potent CRHR1 antagonist, NBI 30775, suggested antidepressant efficacy whereas no side effects were observed. Therefore, different compounds with CRHR1 antagonist activity have been developed by the pharmaceutical industry.

Another component of the HPA-axis also regulated by the MR is arginine vasopressin, which regulates ACTH production and potentiates CRH effects (*see* Fig. 125-2). The arginine vasopressin receptor (V1b) is expressed in brain areas involved in mood and anxiety. An orally active nonpeptide inhibitor of V1b, SSR149415, produces anxiolytic and antidepressive-like effects in a rat model. Therefore, V1b is another component of the HPA-axis with a promising potential as an antidepressant target.

THE CALCIUM SIGNALING HYPOTHESIS

One of the cellular mechanisms thought to be involved in the etiology as well as the therapeutic treatment of depression is LTP. This phenomenon consists in the long term, activity-dependent enhancement of the synaptic response. The mechanism requires the entry into the cell of calcium current. There are many ways in which calcium can enter cells; the one most commonly associated with LTP is the glutamate *N*-methyl-D-aspartate (NMDA) receptor. However, other calcium channels could also play a part in LTP. Inside the postsynaptic terminal, calcium binds to calmodulin and activates α-Ca^{2+}/calmodulin-dependent protein kinase (CaM kinase) II, the most abundant neuronal kinase (Fig. 125-3). CaM kinase phosphorylates itself to maintain an activated state and also phosphorylates other substrates such as α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate receptors, providing a molecular basis for the increased conductance at the synaptic terminals during LTP. Many studies link LTP and calcium signaling to stress, anxiety, and depression as well as concerning antidepressant effects. Stress induced by inescapable electric shocks reduces LTP in the rat hippocampus. Within the hippocampus, the dentate gyrus seems to play a particularly important role in the vulnerability to stress. An increased synaptic efficacy in the dentate gyrus is associated with successful coping with stressful experiences. The calcium signaling hypothesis proposes that antidepressant treatment works by restoring a normal mechanism of coping with stressful events at the hippocampal level (*see* Fig. 125-3). This mechanism requires calcium signaling and LTP that in turn modulate the effects of monoamine neurotransmission in the hippocampus. In support of this hypothesis, monoaminergic afferent pathways modulate the induction and decay of LTP in the dentate gyrus. Fluoxetine treatment and electroconvulsive shock, which produce antidepressant-like effects, modulate LTP in the dentate gyrus.

One mechanism through which antidepressants could modulate LTP is the regulation of calcium entry through NMDA receptors. In fact, several antidepressants downregulate NMDA-subunit expression, including the glycine-binding sites. Interestingly, these effects happen mainly in the cerebral cortex but not in the

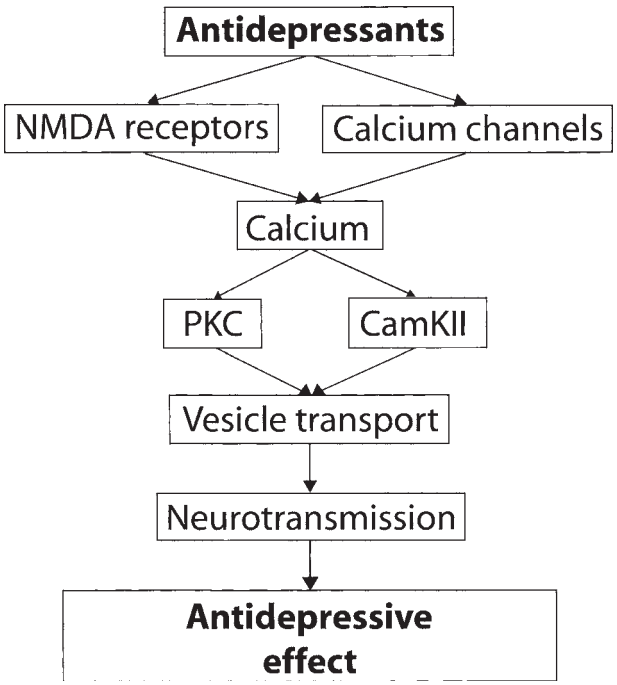

Figure 125-3 Schematic diagram of the role of calcium signaling activated by antidepressants in the regulation of neurotransmission and mood. PKC, protein kinase C; NMDA, *N*-methyl-D-aspartate; CAMK II, Ca^{2+}/calmodulin-responsive kinase II.

hippocampus. Only imipramine inhibits ε2 expression in the hippocampus but this inhibition does not happen in the dentate gyrus. Therefore, other antidepressant-regulated targets should regulate calcium currents in the dentate gyrus. The identification of tissue-specific and drug-responsive targets in the calcium signaling remains a challenge that could lead to novel antidepressant compounds.

UNIFYING THEMES IN ANTIDEPRESSANT SIGNAL TRANSDUCTION

The major components in the monoamine mechanism, the corticosteroid and calcium signaling pathways, show a high degree of crosstalk. As mentioned, an important interaction between the corticosteroid and monoamine pathways derives from different antidepressants' ability to induce an early increase in the mineralocorticoid binding capacity that is necessary for CRH downregulation by antidepressants and precedes the antidepressant effect. Initial clinical data further emphasize the importance of MR upregulation for the antidepressant effects because spironolactone, an MR antagonist, impairs the therapeutic effects of amitryptiline on patients with major depression. One mechanism by which antidepressants modulate the activity of corticosteroid receptors is through the regulation of chaperones, which bind corticosteroid receptor and control their activity and trafficking. Antidepressants can also modulate the expression of CRH through the cAMP pathway that leads to CREB activation. A functional site for CREB has been described in the CRH promoter. Therefore, a desensitization of this mechanism could play a role in antidepressant effects. More extensive and complex are the effects of glucocorticoids at different levels of the monoamine and BDNF cascade. The antidepressant venlafaxine may counteract an altered crosstalk between both pathways by inhibiting CREB phosphorylation and, therefore, could produce an antidepressant effect. All these data together indicate that antidepressants modulate the negative feedback of the HPA-axis at different levels resulting in a normalization of this axis that correlates with therapeutic effects.

PATHWAYS THAT BLOCK ANTIDEPRESSANT ACTION

The most direct way to define the pathways that are specific for the regulation of mood without affecting other biological processes is to analyze the effects of the blockade of these pathways and observe the impact on the antidepressant effects. Transgenic mice with a 90% reduction in CREB activity are viable and do not show an overt phenotype. Surprisingly, these mice show a therapeutic response after antidepressant treatment although they do not show an increase in BDNF. Therefore, in these mice, the therapeutic effect of antidepressants seems to be independent from BDNF upregulation by CREB. BDNF deficient mice develop hyperphagia and aggressiveness related to alterations in serotonergic neurons. However, depressive-like symptoms and antidepressant effects at the behavioral level have not been examined.

Therefore, if the phosphorylation of CREB by PKA and subsequent BDNF upregulation do not play a role in antidepressant action, other PKA substrates might mediate the therapeutic effects of antidepressants. One such PKA substrate is DARPP-32, which is phosphorylated by PKA in response to dopamine and cAMP or in response to antidepressant treatments. Importantly, the knockout of DARPP-32 shows a significant reduction in the therapeutic action of antidepressants. Therefore, DARPP-32 mediates at least in part the antidepressant effects of monoamines. However, DARPP-32 might not be a good drug target because it acts as a potent PP-1 inhibitor through protein–protein interactions that are not easily pharmacologically manipulated. Moreover, the inhibition of PP-1 results in the alteration of many important biological functions as demonstrated by the lethality of the PP-1-deficient mouse.

However, transgenic mice with altered expression of factors related to the corticosteroid hypothesis provide evidence in favor of the involvement of this pathway in antidepressant action. CRHR1-deficient mice show reduced anxiety-related behavior. Consistent with these observations, CRH overexpressing mice show increased anxiety-related behavior. Loss of GR function in the nervous system impairs the HPA-axis regulation, resulting in increased glucocorticoid levels that lead to an impaired behavioral response to stress and display reduced anxiety. The specific overexpression of GR in the brain leads to an increase in anxiety-like behavior. Moreover, clinical evidence indicates that a normalization of the HPA-axis precedes the successful response to antidepressant therapy.

OTHER MECHANISMS OF ANTIDEPRESSANT ACTION

Substance P (neurokinin 1) and its receptor (NK1) are involved in the etiology of depression and NK1 antagonists have shown antidepressant-like effects. Substance P and NK1 are expressed at high levels in the brain, including brain areas thought to be involved in depression such as the amygdala. Anxiety-like behavior is produced by the administration of NK1 receptor agonists, which is indirect evidence that NK1 is involved in depression. Moreover, some reports show antidepressive-like effects of NK1 antagonists although there is still controversy in the field. An initial clinical study with the NK1 antagonist MK-869 showed antidepressive effects similar to that of paroxetine. However, the antidepressant effects of NK1 antagonists have not been confirmed in other clinical settings.

Different components of the Wnt signal transduction pathway are connected to mechanisms that control mood. *Wnt* genes encode secreted proteins that bind to membrane receptors of the Frizzled family. The stimulation of this pathway leads to the activation of the lymphocyte enhancer factor (LEF)/T-cell factor-β-catenin system. A mediator of this pathway is the glycogen synthase kinase 3b. This enzyme is a target for the mood stabilizer lithium chloride. However, there is controversial evidence about the involvement of this pathway in psychiatric disorders.

Melanin-concentrating hormone and its receptor are involved in the control of food intake. MCH1-R is expressed in brain areas that control not only feeding behavior but also mood and stress, including the hippocampus and amygdala. Recently, a melanin-concentrating hormone antagonist has been developed and tested in mice showing a decrease in body weight as well as anxiolytic and antidepressant effects. Therefore, the melanin-concentrating hormone and its receptor defines a novel pathway having antidepressive effects and it constitutes a further mechanism that coordinates feeding behavior and mood.

CONCLUSIONS

After target identification, the relatively large number of candidate genes requires a selection and prioritization process. Criteria to select candidates for further validation should include drug responsiveness as the highest priority. Therefore, the prioritized targets should belong to categories of genes known to be modulated by small compounds such as G protein-coupled receptors or protein kinases. To ensure a reduced number of side effects after long-term treatment, a target gene should have an expression pattern specific for the brain structures involved in depression. One further criterion to validate candidate targets is their regulation by stress, anxiety and antidepressant treatment. If the activity of a target gene is important for the control of mood, this activity should correlate with different alterations of mood as they happen in models of stress and anxiety. Genes found by unbiased approaches should be validated using accepted models of depressive-like behavior. These models are based on the previously discussed hypotheses, such as CRH overexpressing mice, which have high anxiety. Therefore, a combination between unbiased and hypothesis-driven research is needed to accomplish the complete process of functional target validation. The gold standard for a candidate target to be validated for the treatment of depression would be the observation of the specific impact that its modulation has on mood. To prove this point, it is necessary to produce transgenic mice with an altered expression of the candidate target and examine the effects of this alteration in depressive-like behavior.

Some of the target identification and validation approaches have intrinsic advantages. For example, genetic linkage results in targets related to depression in the human population. Targets found by other means need to be validated in humans. This procedure can be achieved using single nucleotide polymorphism analysis and association studies to complement neuroanatomic and behavioral data from animal models.

Different hypotheses explain the etiology of depression. Each focuses on different biological processes that contribute to explain the clinical manifestation of depression and connect the regulation of mood to other biological processes such as the stress response and feeding behavior. Most likely, these different signaling pathways converge at a certain point to specifically control mood. This convergence point may control neurotransmission, in particular, LTP in the hippocampus. This opens the possibility that by dissecting pathways activated by antidepressants it would be possible to find new targets for novel drugs with a direct and specific mechanism of action, likely producing novel antidepressants with a higher potency, a faster action and fewer side effects.

126 Anxiety Disorders

GREGORY M. SULLIVAN AND JACK M. GORMAN

SUMMARY

The anxiety disorders involve dysfunctional brain processes that offer prime targets for molecular therapeutics borne from neuroscience research. First, a brief historical overview of existing therapeutic agents for anxiety disorders is provided, and phenomenological descriptions of the major anxiety disorders are summarized. Next, brain circuitry relevant to the anxiety disorders is described, emphasizing the findings of neuroscience research on stress and conditioned fear. Molecular targets in the brain's neuropeptide and amino acid transmitter systems are then detailed, and plausible future targets are discussed. This chapter is intended to impart some of the exciting translational research advances and drug development in the anxiety disorders.

Key Words: PTSD; panic disorder; social anxiety disorder; generalized anxiety disorder; obsessive-compulsive disorder; amygdala; hippocampus; prefrontal cortex; neurokinins; corticotropin-releasing factor; GABA; glutamate.

INTRODUCTION

Sigmund Freud believed that the basis of mental illness would eventually be shown to lie in aberrant brain function. Yet the tools were not available in his time to understand or treat behavioral pathology through a physiological approach. A century later the understanding of brain function has grown immensely, and there is a boom of pharmacological research and drug development aimed at targeting the disabling symptoms of psychiatric disorders.

It is well established that anxiety disorders occur at high prevalence and impose significant health burdens. Medication management of the symptoms is often necessary, and, although there are several medication classes with proven efficacy, available treatments have significant drawbacks and do not work for all patients. Therefore, there is an ongoing need for improved anti-anxiety agents. It is desirable to target the dysfunctional neurobiological systems responsible for the disorders in the most specific manner, and, ideally, anxiolytics should have high therapeutic efficacy for a large percentage of patients with a given anxiety disorder although being safe and tolerable. This chapter presents a brief history of anxiolytic medications, reviews developments in the neurobiological understanding of anxiety disorders, and indicates what anxiolytic drug developments to expect in this age of molecular medicine.

HISTORICAL OVERVIEW OF ANXIETY DISORDER THERAPEUTICS

In the second half of the last century the "psychopharmacological revolution" in psychiatry began with a series of serendipitous discoveries of the medications with therapeutic efficacy for particular psychiatric disorders. These early discoveries provided the forerunners of virtually all-available medications for anxiety and affective illnesses. Through such discoveries it became evident that symptoms of particular "psychological" disorders, including anxiety disorders, could be reversed by administration of a medicinal agent. This implied that the neurobiological substrates affected by these medications were likely involved in the disorders treated. For example, in the 1950s iproniazid, then in use as an antituberculosis agent, was noted to have mood elevating properties by investigators in the United States. This led to the eventual understanding that drugs like it acted as antidepressants by inhibition of monoamine oxidase, an enzyme responsible for degradation of several monoamine neurotransmitters. In 1957, the antidepressant properties of the tricyclic compound imipramine, an agent that inhibits neuronal reuptake of the monoamines serotonin and norepinephrine, were reported by a Swiss clinical researcher. A few years later in the United States, imipramine was reported as a treatment for the anxiety condition that was to become known as panic disorder, and French clinicians had begun using monamine oxidase inhibitors (MAOIs) for this condition. Establishment of the tranquilizing properties of meprobamate in the 1950s was shortly followed by the introduction of another class of anxiolytic agents, the benzodiazepines (BDZs); and soon BDZ agents such as chlordiazepoxide and diazepam were widely available therapeutic options for anxious behaviors. This era firmly established that the anxiety disorders had a basis in abnormal brain function.

Unfortunately, these treatments were not without liabilities. The side effect profiles of the tricyclic antidepressants and MAOIs were often undesirable. Moreover, the tricyclics could produce deadly cardiotoxicity in overdose of less than 10 times a typical daily dose, a particularly critical issue when treating patients at risk for suicide attempt. The MAOIs could lead to a deadly hypertensive crisis by ingestion of common foods containing high amounts of the vasoactive amine tyramine, which would otherwise be metabolized by MAO in the gut. The addicting qualities of BDZs such as the infamous "mother's little helper," diazepam, also soon became apparent. The subsequent decades saw introduction of "me too" drugs, i.e., the development of agents based on

the molecular structures and pharmacodynamics of the agents already identified. Even the more recent introductions of the selective serotonin reuptake inhibitors (SSRIs), selective norepinephrine reuptake inhibitors, and newer agents with both properties can be considered simply as improved versions of the tricyclic antidepressants.

Diverse scientific disciplines are presently converging on common understanding of behavioral pathology in the anxiety disorders in terms of brain dysfunction. These disorders are particularly well positioned among psychiatric conditions to benefit from this second stage of the psychopharmacological revolution. In particular, there are validated animal models for anxious, fearful, and avoidant behaviors, making drug design and development more like that found in other areas of medicine in which basic models often drive development of therapeutics. Neuroscience research has been providing a rapidly improving understanding of the neural circuits, cellular events, and molecular mediators of cognitive functions, emotional expressions, and behavioral adaptations to stressors. At the same time, biological studies of particular anxiety disorders have identified involved neurochemical, endocrine, and autonomic systems. Advances in neuroimaging techniques are beginning to allow in vivo quantitative assessment of regional structural, functional, and neurochemical abnormalities in the brains of patients with a wide array of psychiatric conditions including the anxiety disorders. Therefore, with these developments, a rational scientific approach to the anxiety disorders is made possible by immensely improved understanding of brain pathophysiology in the anxiety disorders and many novel approaches are on the horizon.

CLINICAL PRESENTATIONS OF THE ANXIETY DISORDERS

Post-traumatic stress disorder (PTSD*)* is characterized by a symptom constellation that develops following an emotionally traumatic event that involves threat of injury, bodily harm, or death to oneself or others. The emotional response to the event should by definition involve intense fear or helplessness. Importantly, three main categories of symptoms should result: re-experiencing of the trauma in the form of images, nightmares, or flashbacks; persistent avoidance of trauma-related thoughts, activities, situations, or people, including detachment from others or psychological numbing; and symptoms of hyperarousal such as exaggerated startle, insomnia, irritability, or hypervigilance.

Panic disorder has as its core clinical feature the occurrence of panic attacks, bursts of rapidly developing fear or discomfort occurring in a crescendo pattern and accompanied by distressing cognitive and somatic symptoms. Often these include dyspnea, heart pounding or racing, sweats, trembling, dizziness, gastrointestinal disturbance, and feelings of unreality or urge to flee. Essential for a diagnosis of panic disorder is interpanic attack worry about the occurrence of future attacks or the medical implications of the attacks, or there is phobic avoidance of situations in which another attack is believed likely to occur. Avoidance of situations that have become associated with attacks, such as crowds, elevators, bridges, is common.

Social anxiety disorder is characterized by excessive fear of social or performance situations. The fear centers around behaving in social situations in a way that will be humiliating or embarrassing, and the situations are avoided or else endured with intense distress or anxiety.

Generalized anxiety disorder is characterized by excessive anxiety or worry about a number of events or situations that occur more days than not for at least 6 mo. The patient has difficultly controlling the worry and there are several associated symptoms such as becoming easily fatigued, irritability, poor concentration, muscle tension, and sleep disturbance.

Obsessive-compulsive disorder (OCD) is characterized by the presence of intrusive thoughts or impulses. The obsessions, although usually recognized by the patient as excessive and products of their own mind, are usually accompanied by anxiety. This in turn often prompts ritualized behaviors that are performed in an effort to neutralize the obsessions or the associated anxiety. The obsessions and compulsions cause marked distress and consume significant amounts of time. Obsessions typically fall into several broad categories, including checking, ordering, or counting; preoccupation with contamination; aggressive or horrific impulses (such as hurting one's own child); or sexual imagery. In all of these anxiety disorders the impairment should be of a substantial level such that the disorder directly results in significant interference with work and/or social functioning.

BRAIN CIRCUITRY AND ANXIETY

An understanding of the neural correlates of anxiety is facilitated by an understanding of the stress response systems. An inherent assumption in this approach to anxiety disorders is that they involve dysfunction in phylogenetically conserved systems for response to adversity, whether real or imagined. Stress comes in many forms including physiological stressors, such as hemorrhage or ingestion of a toxin, and psychological stressors, such as sensory stimuli that the brain has learned are predictive of imminent danger. Over 50 yr ago, Hans Selye made the seminal observation that rather diverse stressors appear to activate a common stress response system with resulting hypertrophy of the adrenal glands and involution of immune structures such as the thymus gland. Although there are elements of differential physiological response that depend on the nature of the stressor, central commonalities are more the rule. For example, the hypothalamic–pituitary–adrenal (HPA) axis and the *locus ceruleus*-based noradrenergic system are the two main arms of a common stress system response to diverse stressors. Efferent neurons from the locus ceruleus activate the autonomic nervous system through both the sympathetic-adrenomedullary branch and the parasympathetic branch. HPA activation results in systemic glucocorticoids release whereas *locus ceruleus*-based noradrenergic system activation results in systemic release of epinephrine. The multiorgan pathology observed by Selye is explained by excessive activity of the HPA axis, leading to adrenal hyperplasia, and the inhibitory effects of an activated stress system on aspects of immune function, resulting in immune organ involution. Exposure to stress, particularly of an uncontrollable type, also results in increased release of the neurotransmitter norepinephrine in stress-responsive brain regions that include prefrontal cortex (PFC), hypothalamus, amygdala, hippocampus, and locus ceruleus. Many aspects of anxiety disorders' pathophysiology appear related to overactivity of components of the stress response system.

Neuroscience study of the emotional circuits underlying fear and anxiety has largely focused on Pavlovian fear conditioning and fear-potentiated startle, in part because the brain processes underlying these behavioral phenomena are readily studied in rodent models at anatomical, cellular, and molecular levels. These types of fear learning involve a coordinated network of brain structures, and the temporal lobe structure known as the amygdala plays a central role. Sensory information is relayed to the amygdala via two main

paths: a fast, direct, monosynaptic route from sensory areas of thalamus, rapidly providing crude information to the amygdala that may initiate a fear response; and a slower, polysynaptic route from thalamus to sensory cortex to amygdala, which involves cortical processing of sensory information, thus delivering more complex information about the stimuli, which may provide for a more appropriate amygdala response. Fear learning occurs at the level of the amygdala when stressful stimuli, become associated with other previously innocuous stimuli. Such learning is encoded by structural changes in synaptic connections between neurons (synaptic plasticity), so that the previously innocuous stimuli become sufficient to activate fear responses in the future. The amygdala, in turn, activates in a parallel manner a set of brain regions, which mediate specific components of the fear response. For example, amygdala activation of subregions of the hypothalamus results in aspects of the neuroendocrine and autonomic responses. Amygdala activation of the periaqueductal gray results in the freezing behavioral response as well as hypoalgesia. The hippocampus is essential for conditioned fear responses to contexts (complex representations of the environment). The hippocampus relays encoded contextual information to amygdala via the bed nucleus of the stria terminalis (BNST), a region often viewed as an anatomical extension of the amygdala. Contextual learning and memory may be particularly relevant to PTSD and panic disorder in which environmental stimuli often can illicit intense anxiety reactions.

Fear extinction is a process whereby reexposure to a conditioned stimulus results in a progressively diminishing conditioned response because new learning indicates the stimulus is no longer predictive of the aversive unconditioned stimulus. Recently, more work has focused on the brain processes underlying extinction because psychotherapies with proven efficacy in several anxiety disorders, such as cognitive-behavioral therapy, appear to employ the extinction circuitry in the reduction of inappropriate anxiety responses. The ventromedial region of PFC appears to be involved in the consolidation and/or storage of extinction memory. This region has robust projections to local γ-aminobutyric acid (GABA) ergic neurons in amygdala that, in turn, exert powerful inhibitory control on the output nucleus of the amygdala. This region of PFC is thought to play a role in higher order brain processing of emotionally salient stimuli, modifying the behavioral response based on reward and threat contingencies and the prediction of social and survival outcomes. For example, it has been suggested that there is deficient PFC-mediated inhibition of subcortical fear structures in certain anxiety disorders such as social anxiety disorder and PTSD.

OCD, although grouped with the other anxiety disorders in the *Diagnostic and Statistical Manual-IV-TR*, appears to involve largely separate neurobiological circuitry from the other anxiety disorders. In particular, research has focused on pathology in cortico–striato– thalamic–cortico processing loops. Here the striatum is proposed to play a critical role in facilitating information processing at the level of thalamus by both enhancing and filtering the throughput, thereby determining the level of conscious perception necessary for certain cognitive and behavioral functions. Striatal–thalamic interactions are viewed as performing a filtering function, lessening the load on limited conscious resources by reducing the allocation of such resources for autonomic, rule-based, stereotyped processes. In this model, dysfunction in this system in OCD causes inadequate filtering, resulting in excessive conscious perception of what should under normal circumstances be processed nonconsciously and not require engagement of higher brain systems or emotional response.

MOLECULAR TARGETS IN THE NEUROPEPTIDE SYSTEMS

Many of the existing medication treatments for the anxiety disorders involve sites of action in the serotonin and norepinephrine systems. Because extensive focus on these systems has been reviewed in detail elsewhere, readers are directed to referenced reviews for information on pharmacological developments involving targeting of these two monoaminergic systems. This section focuses on neuropeptide systems as emerging targets of neuropsychiatric drug development.

Although it has been know for some time that the hypothalamic releasing factors (with the exception of dopamine) are neuropeptides, it has become increasingly evident that several neuropeptides are distributed more widely than the hypothalamus and pituitary. These neuropeptides play roles in diverse brain functions, and several are involved in stress responding and emotional reactivity. Because these peptides generally tend to increase such responsiveness, much focus has been placed on targeting their receptor sites with synthetic antagonists that reduce response to stressful stimuli. The antagonists reviewed below highlight the systematized approach to new drug development in anxiety disorders. Animal models have allowed identification of the key molecular targets and have guided the development of candidate drugs from bench to clinical testing. Focus is placed on the systems in the more advanced stages of clinical development for anxiety disorders.

CORTICOTROPIN-RELEASING FACTOR ANTAGONISTS

Corticotropin-releasing factor (CRF) is a 41-amino acid peptide that was first described for its endocrine role in the HPA axis response. It is now known that plays a much wider role in the coordinated response of behavioral, autonomic, neuroendocrine, and neuroimmune responses to stress. On exposure to stress, parvicellular neurons of the paraventricular nucleus of hypothalamus release CRF and arginine vasopressin into the portal circulation. They travel to target receptors in the pituitary, stimulating secretion of adrenocorticotropic hormone into the main circulation. Adrenocorticotropic hormone travels to the adrenal glands and stimulates secretion of glucocorticoids.

In addition to its role in the HPA axis response, CRF also acts as a neurotransmitter or neuromodulator at several other target sites in the brain including sites involved in fear and anxiety such as cortical areas, amygdala, BNST, hippocampus, nucleus accumbens, dorsal raphe nucleus, and locus ceruleus. There are several related neuropeptides to CRF including urotensin and the urocortins, which, despite having only four amino acids in common, share secondary structure that appears to determine the similar bioactivities. CRF and its relatives act by stimulating G protein-coupled receptors CRF_1 and CRF_2; CRF_2 has three functional splice variants, $CRF_{2A–C}$. Another player in this complex array is the CRF-binding protein that tightly binds both CRF and urocortin and is thought to modulate the activity of these neuropeptides by limiting activity at the target receptors.

CRF_1 receptors are distributed widely in the brain including in cortex, hypothalamus, pituitary, amygdala, hippocampus, cerebellum, and locus ceruleus. CRF_2 receptors have a more limited distribution to subcortical areas such as hypothalamus, amygdala, hippocampus, lateral septum, and choroid plexus; and there appears to be no cortical expression of CRF_2. It is important to note, however, that the distributions of mRNA and protein product

of these CRF receptors differ considerably between rodent and primate, presumably also reflecting difference in function in some instances. In animal models, anxiety-related behavioral effects of CRF involve activity at CRF_1 receptors. For example, inhibiting CRF_1 expression with antisense oligonucleotides to its RNA or blocking the CRF_1 receptor with synthetic nonpeptide antagonists produces anxiolytic-like responses when challenged in several anxiety behavior paradigms. Also, a CRF_1 receptor knockout mouse has been created that has reduced anxiety-related behaviors. The role of CRF_2 receptors in anxiety is not as straightforward, but animal models have demonstrated a role in particular anxious behaviors.

In humans, CRF levels are reported to be elevated in the cerebrospinal fluid in several psychiatric conditions including depression and PTSD, and both of these conditions evidence abnormal responsivity of the HPA axis. High levels of circulating glucocorticoids can produce dendritic atrophy in hippocampus, an area of the brain involved in cognitive functions such as memory and spatial perception as well as emotional responses. It is not known if neurotoxicity resulting from heightened or prolonged glucocorticoid responses occurs in humans, but there is some evidence from morphometric MRI studies for smaller hippocampal volume in PTSD and possibly also depression.

Because of the wealth of evidence from preclinical studies and more limited evidence from clinical research, the CRF receptors have been prime targets for anxiolytic drug development. One of the earlier nonpeptide CRF_1 receptor antagonists, R121919 was demonstrated to have anxiolytic and antidepressive properties in a sample of patients with clinical depression, but, although well tolerated, emergence of liver toxicity halted development of the compound. Yet a host of other peptide and nonpeptide antagonists have been studied that have differential activities at the CRF_1 and CRF_2 receptors. Antagonists of central arginine vasopressin receptors are also in development. These new classes of agents will likely offer specific targeting of the stress response system for the purpose of anxiolysis in specific anxiety disorders.

NEUROKININ ANTAGONISTS Substance P is an 11-amino acid peptide found in brain, sensory afferents, lungs, and gut. Key limbic areas in which it is found include hypothalamus, amygdala, hippocampus, periaqueductal gray, and locus ceruleus. Like other neuropeptides, substance P is found colocalized within neurons that contain neurotransmitters such as glutamate, 5-HT, and acetylcholine, and it appears to have a modulatory role on their release. Substance P is secreted in response to stress, and central administration of substance P increases fearful behavioral and autonomic responses in the rodent. Therefore, animal models point to a role in anxiety and the anxiety disorders. The receptor to which substance P binds with highest affinity is the neurokinin (NK) 1 receptor. Direct effects of substance P are on glutamatergic neurons, which in turn alter activity in monoaminergic and opioid neurons in directions that are anxiogenic. Therefore, targeted disruption of the NK-1 receptor has been an area of intense drug development for anxiety conditions, and animal models have confirmed an anxiolytic profile for NK-1 antagonists in multiple behavioral models of stress and anxiety. NK-2 and NK-3 receptor antagonists are also in development with potential applications in the anxiety disorders. The NK-1 antagonist GR205171 was demonstrated to have a significant response rate, similar to an SSRI, in a placebo-controlled trial of social anxiety disorder. Notably, pre- and post-treatment neuroimaging indicated the anxiolytic effects were accompanied by post-treatment reductions in cerebral blood flow response to public speaking challenge in the medial temporal lobe region that includes amygdala and hippocampus. In one clinical trial in patients with depression, an antagonist to NK-1 had greater antidepressant activity compared with placebo, equal antidepressant efficacy compared with an SSRI, and robust anti-anxiety effects. Other neurokinin antagonists are in clinical trials including an NK-1 antagonist for generalized anxiety disorder and an NK-3 antagonist for phobias.

NEUROPEPTIDE Y Neuropeptide (NP)Y is expressed at high levels in brain areas including cortical areas, hypothalamus, amygdala, hippocampus, nucleus accumbens, and locus ceruleus. NPY belongs to a family of peptides that include pancreatic polypeptide and peptide YY. There are at least three receptor subtypes for NPY in the central nervous system (CNS), Y1, Y2, and Y5. The Y2 receptors can be found on NPY-expressing neurons in which they act as autoreceptors; therefore antagonism of the Y2 autoreceptors potentiates the release of NPY. NPY knockout mice show more anxious-like behavior whereas mice overexpressing NPY appear more resistant to effects of stressful challenge, suggesting a role in stress resilience. Further, NPY and Y1 knockout mice consume more alcohol than wildtypes whereas NPY overexpressing mice or potentiation of NPY by Y2 autoreceptor antagonism evidence decreased consumption. This may be clinically relevant because there is high comorbidity of alcohol use disorder and anxiety disorders. NPY is colocalized with norepinephrine in a number of brain regions. Work in animal models suggests NPY has anxiolytic activity via a mechanism that involves the noradrenergic system, and chronic stress appears to lower basal plasma NPY level and blunts its increase to acute footshock stress. In a small study of combat veterans with PTSD, low basal NPY and blunted NPY response to the α-adrenergic antagonist yohimbine was reported. Therefore, it is possible that targeting the NPY system may be useful in the treatment of PTSD.

GALANIN Galanin is a peptide found to colocalize in noradrenergic neurons of the locus ceruleus and 5-HT neurons of the raphe nuclei in which it appears to act as an inhibitory neuromodulator of these monoaminergic systems. It is expressed in hypothalamus, amygdala, BNST, and hippocampus. There are at least three receptor subtypes for galanin, GAL1, GAL2, and GAL3. In animal models galanin gene expression is upregulated by chronic stress. Galanin knockout mice have increased anxiety-related behavior in particular behavioral paradigms, whereas those overexpressing galanin appear resistant to the anxiogenic effects of noradrenergic challenge. Yet effects on anxiety-related behaviors, in either direction, appear region specific and pathway specific, making development of therapeutics targeting this system quite challenging. The close relationship of galanin and noradrenergic activity has led to the suggestion that this system might be of particular value for molecular targeting in the anxiety conditions associated with high noradrenergic activity, namely PTSD and panic disorder.

CHOLECYSTOKININ Cholecystokinin (CCK) is a polypeptide found in both the gastrointestinal tract and the brain, in which it is present in a variety of biologically active forms that are derived from a 115-amino acid precursor molecule, prepro-CCK. In brain, CCK is colocalized with other neurotransmitters, particularly GABA and dopamine, and GABA appears involved in the regulation of CCK release. Because CCK stimulates both cortical and hippocampal neurons, effects blocked by BDZs, interest developed in its anxiogenic effects. CCK_1 and CCK_2 are two

described receptors for CCK peptides. Cholecystokinin tetrapeptide (CCK-4) is a four amino acid peptide cleaved from the amino terminus of CCK. It has selective activity at the CCK_2 receptor, and it produces anxiety-related behaviors in a variety of animal models. CCK-4 has high binding in the PFC and temporal cortex, moderate binding in hypothalamus, nucleus accumbans, and portions of hippocampus, and low to moderate binding in amygdala and locus ceruleus. CCK-4 has been used in the clinical laboratory to induce panic attacks in anxiety disorder patients, although it is not clear if this is owing to central or peripheral actions of the peptide. Panic disorder patients and, to a lesser extent, PTSD and social anxiety disorder patients are more sensitive to its panic producing effects than healthy volunteers. It is notable that endogenous CCK level has been shown to be lower in cerebrospinal fluid of patients with panic disorder than in controls. Therefore, the central CCK receptor system is another potential target for therapeutic agents in anxiety disorder. Several nonpeptide antagonists that work at CCK_1 and CCK_2 receptors are under development.

MOLECULAR TARGETS IN THE AMINO ACID TRANSMITTER SYSTEMS

γ-AMINOBUTYRIC ACID The neurotransmitter GABA is the predominant inhibitory neurotransmitter throughout the brain. GABA is synthesized from the amino acid precursor glutamate. The two receptor subtypes for GABA are the $GABA_A$ and $GABA_B$ receptors. The $GABA_A$ receptor complex is a multisubunit receptor with a central ligand-gated chloride ion channel. Binding of presynaptically released GABA to the postsynaptic $GABA_A$ receptor increases movement of negatively charged chloride ions into the postsynaptic neuron so that it becomes hyperpolarized and therefore less likely to fire. The $GABA_A$ receptor is allosterically modulated by a number of neighboring receptors in the lipid bilayer, one of the best described being the BDZ receptor. $GABA_B$ is a G-protein coupled receptor that appears to have an autoreceptor feedback function in that it is found on presynaptic neurons and is involved in inhibition of GABA release into the synapse, although $GABA_B$ is also found at postsynaptic sites. The muscle relaxant baclofen binds selectively to the $GABA_B$ receptor, and a rodent model suggests a role of this receptor in panic-like responses mediated by the periaqueductal grey.

The BDZ anxiolytics were the first widely prescribed antianxiety medications. There are at least five subtypes of BDZ receptors, and they appear to be differentially distributed in brain. These BDZ receptors are positive allosteric modulators of fast inhibitory neurotransmission by GABA at $GABA_A$ receptors. There is a BDZ receptor binding site on the $GABA_A$ receptor, which, when BDZ is bound, changes the conformation of the GABA binding site amplifying the effect of GABA binding on conductance of chloride through the ion channel. There are also other modulatory sites near the $GABA_A$ receptor that bind alcohol and barbituates as well as the convulsant picrotoxin. The complex formed by the BDZ receptor and $GABA_A$ receptor is often referred to as the $GABA_A$–BDZ complex. Actions of BDZs at the BDZ receptor are thought to be responsible for their anxiolytic actions and anticonvulsant and muscle relaxant properties. The potentiating effects of alcohol are problematic if BDZs are present, as excessive hyperpolarization of postsynaptic neurons throughout the CNS may lead to life-threatening suppression of brainstem autonomic control of cardiorespiratory function. Also, rapid withdrawal of BDZ and/or alcohol may lead to widespread closure of the choride ion channel such that postsynaptic neurons are maximally depolarized and more excitable than normal. The spectrum of severity of such a state ranges from increased anxiety to classic withdrawal symptoms to cardiorespiratory dysregulation and/or seizure, and, in some instances, death.

The $GABA_A$ receptor complex is made up of five protein subunits made up of a variety of combinations of the subunit types, termed α, β, γ, δ, and ρ. Mouse knockouts of individual subunits have given clues to the various physiological effects of the $GABA_A$ receptor complex and suggested more specific molecular targets. For example, knockout work indicates the α-1 subunit is more relevant to the anticonvulsant, sedative, and amnestic properties of BDZs but less relevant to the anxiolytic and muscle-relaxant properties. Agents selective for this subunit type, such as the popular non-BDZ sedative zolpidem (Ambien), may explain the strong sedative qualities and apparent relative lack of anxiolytic properties.

Abundant clinical evidence exists for GABA system dysfunction in anxiety disorders, in particular in panic disorder and PTSD. It is not clear to what degree this indicates primary pathology, secondary compensatory change, or even the effects of long-term BDZ treatment or other psychotropic treatment. Yet newer agents are being explored that act by different GABAergic mechanisms such as inhibition of GABA reuptake at its transporter site as well as inhibitors of GABA catabolism. Clinical trials are underway for a partial agonist at the BDZ–GABA receptor complex in panic disorder and generalized anxiety disorder, and a GABA reuptake inhibitor is in trials for generalized anxiety disorder. Also, $GABA_A$ receptor subunit targeting may offer more selective targeting of anxiety without unwanted sedative and cognition impairing effects.

GLUTAMATE Glutamate is the major excitatory neurotransmitter throughout the CNS, responsible for functioning of up to 40% of synapses. The two major classes of glutamate receptors are the ion channel (or ionotropic) glutamate receptors, including *N*-methyl-D-aspartate, α-amino-3-hydroxy-5-methylisoxazole propionate, and kainate receptors, and the metabotropic glutamate receptors. The ionotropic receptors are generally postsynaptic and mediate fast synaptic transmission through sodium and calcium permeable ligand-gated ion channels. These channels are also involved in synaptic plasticity in which structural changes in synapses are induced through processes dependent on gene transcription and new protein synthesis. The metabotropic receptors appear to modulate activity of the ionotropic receptors via actions at pre- and postsynaptic sites as well as presence on glial cells and GABAergic neurons.

Under development as anxiolytics are agents that modulate glutamatergic activity through actions on either metabotropic receptors or ionotropic receptors. There are also several existing anticonvulsant medications that act through glutamatergic mechanisms. In addition, work in animal models using metabotropic glutamatergic antagonists suggests HPA axis activity in response to stress may be dampened, a potentially beneficial effect in anxiety disorders with evidence for HPA axis hyperresponsivity such as PTSD. Also, D-cycloserine, a partial agonist at *N*-methyl-D-aspartate receptors, facilitates extinction of fear memory in the rodent model. In true bench to bedside work, D-cycloserine was therefore employed as an adjunct to the psychotherapy of specific phobia, with results indicating the drug produced a more rapid response to

the psychotherapy. Agents such as D-cycloserine may therefore prove to be useful adjuncts to psychotherapies aimed at extinguishing anxiety-related behaviors through facilitation of the circuitry mediating extinction.

MOLECULAR TARGETS FOR THE FUTURE

Contrary to neuronal dogma, the adult mammalian brain generates new neurons in hippocampus, the olfactory bulb, and possibly other regions such as an area of PFC. In a region of hippocampus, the dentate gyrus, progenitor cells divide and develop into functional neurons with developed axons, dendritic processes, and form synapses with other neurons. This process, known as *neurogenesis*, continues throughout life. In the hippocampus there appears to be a balance between apoptotic neuronal death and neurogenesis. Neurogenesis appears to be influenced by environmental, endocrine, and pharmacological stimuli, suggesting a role in adaptation and response in the face of stressful challenge. Neurogenesis in mice appears to be stimulated by exposure to enriched environments with greater social interaction, opportunities for new learning, and greater exercise. It may also be stimulated in response to hippocampal-dependent learning tasks. Neurotrophic factors are molecules that play roles in the development, survival during pruning, maintenance, and plasticity of neurons, and, therefore, they are essential to neurogenesis. Brain-derived neurotrophic factor is one of the more abundant neurotrophic factors identified in the CNS. Brain-derived neurotrophic factor is found to be increased in hippocampus in postmortem brains of patients treated with antidepressants. Because treatments for depression all appear to enhance neurogenesis, including the antidepressants, electroconvulsive therapy, and lithium, it has been proposed that enhancement of neurogenesis may be requisite for antidepressant action. At a minimum, enhanced neurogenesis resulting from treatment is evidence of structural changes in neurons that are associated with recovery from depression. Much research is focused on defining the mediators of neurogenesis and whether the process is necessary for recovery from anxious or fearful states similar to the hypothesized role in recovery from depression. Therefore, agents that enhance neurogenesis may be future molecular targets in the development of improved anxiolytics.

CONCLUSION

This chapter provided a brief overview of the progress in pharmacological drug development and molecular targeting in the anxiety disorders. The BDZs and agents influencing synaptic levels of serotonin and norepinephrine have been the primary treatments in clinical use to date, but research in the anxiety disorders, guided by neuroscience research, has suggested novel mechanisms for molecular targeting. Much of the focus of research is based on heuristic neurobiological models of the anxiety disorders derived from preclinical work in the neuroscience of stress and conditioned fear. Although monoaminergic systems have been at the center of focus for much of past drug development, CNS neuropeptide and amino acid transmitter systems offer promising molecular targets for the development of specific, efficacious, safer, and more tolerable therapies.

127 Trauma Spectrum Disorders

CHRISTINE HEIM, J. DOUGLAS BREMNER, AND CHARLES B. NEMEROFF

SUMMARY

Exposure to trauma and pathological responses are influenced by genotype. Despite the inherent difficulties of studying the genetics of trauma-related disorders, the field has exhibited remarkable advances. Identification of polymorphisms in critical genes that influence neurotransmitter systems involved in the stress response is rapidly progressing and will elucidate the nature of gene-by-environment interactions that determine whether an individual develops a disorder in response to trauma. This chapter provides an overview of the status of genetic research on trauma spectrum disorders and discusses clinical implications.

Key Words: Amygdala; comorbidity; depression; endophenotype; gene-environment interaction; hippocampus; hypothalamic-pituitary-adrenal axis; neurobiology; polymorphisms; post-traumatic stress disorder; startle; trauma.

INTRODUCTION

The deleterious effects of stress have become increasingly evident. Surprisingly high rates of traumatic stress occur in our daily lives. Childhood abuse, car accidents, terrorism, combat, rape, assault, and a variety of severe traumas can all be associated with lasting effects on the individual. The American Psychiatric Association defines a traumatic event as an experience that is threatening to the self or someone close to you, accompanied by intense fear, horror, or helplessness. The definition of a traumatic event is outlined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV). Exposure to a traumatic event, defined in this way, is required for the diagnosis of post-traumatic stress disorder (PTSD), making PTSD a psychiatric disorder that by definition is related to, and occurs as a consequence of, a stressful or traumatic event. In addition to PTSD, patients with other disorders exhibit high rates of trauma, including depression, substance and alcohol abuse, anxiety disorders, borderline personality disorder (BPD), and somatic disorders. The diagnosis of these latter disorders does not necessarily require exposure to a traumatic event. However, epidemiological studies have provided strong evidence that stressful life experiences and trauma represent major risk factors for the development of these disorders.

There is a great deal of comorbidity among these disorders, so that a traumatized individual is most likely to fulfill diagnostic criteria for several disorders, for example, PTSD and depression, or PTSD and alcoholism, and so on. The development of the DSM from its inception after World War II has led to a progressive "splitting" of psychiatric disorders into finer and finer categories, from the initial broad psychoanalytical categorization of "neurosis" vs "psychosis." The swing of the pendulum toward this pattern of progressive splitting may have gone too far. Psychiatric disorders may be better represented to the "neurosis-psychosis" dichotomy than the fine-tuned current psychiatric nosology. The neurosis concept would encompass depression, anxiety disorders (including panic disorder, generalized anxiety disorder, and PTSD), personality disorders (including BPD), the somatic disorders, and to a certain extent alcohol and substance abuse disorders, suggesting that there are not separate distinct disorders, but spectra of disorders that have been improperly categorized as distinct disorders by the current diagnostic schema. One such spectrum would be to a variable extent associated with trauma. Taken together, these considerations support the existence of a central "core" disorder that underlies several disorders. Evidence from studies employing neurobiological assessment methods suggests that this underlying core disorder might consist of specific neurobiological alterations that, in the genetically vulnerable individual, are induced by stress or trauma resulting in physiological and behavioral patterns that represent the clinical phenotypes of trauma spectrum disorders. These two views are not mutually exclusive.

Not all individuals who experience a traumatic event subsequently develop psychopathology. Why some individuals develop a psychiatric disorder after trauma whereas others do not remains obscure. Moreover, it is not well understood why some develop PTSD, although others develop depression or another disorder. In most cases, the manifestation of one or more trauma spectrum disorders in response to trauma is influenced by a complex interplay of preexisting vulnerabilities, including genetic predispositions, personality styles, and experiences, as well as psychological and situational factors at the time of the trauma and in the trauma's aftermath. Because the majority of trauma survivors do not develop a disorder, it is crucial to identify vulnerability and resilience factors, including genetic factors. Studies on the genetics of trauma spectrum disorders have been hampered by many factors, such as genetic heterogeneity (e.g., a similar phenotype develops from different genotypes) and incomplete penetrance of the phenotype (e.g., a person with genetic risk for PTSD, who is not exposed to trauma, will not develop PTSD). Despite these difficulties, evidence is accumulating that exposure to trauma and pathological responses to trauma are influenced by genetic composition. There are also advances in identifying molecular genetic

variations that confer risk to develop disorders in response to trauma. Elucidation of the genetics of neurobiological traits that determine to what extent and in which way the brain will respond to a stressor or a frightening situation is progressing. Finally, researchers are beginning to disentangle the continuous interplay between genetic make-up and environmental influences across the life span in shaping phenotypic expressions with vulnerability to stress and disease. This chapter provides an overview of the status of genetic research on trauma spectrum disorders with a focus on PTSD, including the genetics of comorbidity among related disorders. Other disorders frequently related to trauma, such as depression and alcoholism, are covered elsewhere in this section.

POST-TRAUMATIC STRESS DISORDER

According to the DSM-IV, PTSD is characterized by a set of symptoms that develop and persist in relation to the experience of one or more severely stressful or traumatic events. To be diagnosed with PTSD, a person must have experienced a traumatic event. Criterion A in the DSM-IV specifies that a stressful experience is classified as a "traumatic" event if the person experienced an event that involved actual or threatened death or serious injury, or a threat to the physical integrity of the person or others, and if the person responded with fear, helplessness, or horror to the event. Criteria B, C, and D of the DSM-IV define three symptom clusters comprising three types of symptoms that occur in response to the traumatic event in PTSD. These symptom clusters include re-experiencing the event, avoidance of reminders of the event, and hyperarousal. Re-experiencing, also called intrusion, involves recurrent or unwanted memories of the event, such as images, thoughts or perceptions, nightmares or flashbacks related to the event, or intense psychological distress or physiological reactions to reminders of the event. Symptoms of avoidance involve efforts to avoid reminders of the event, such as people, places, thoughts or feelings that are associated with the event. Symptoms of hyperarousal include disturbed sleep, impaired concentration, hypervigilance, and exaggerated startle responses. A diagnosis of PTSD requires at least one symptom from the re-experiencing category, three symptoms from the avoidant category, and two symptoms from the hyperarousal category. The symptoms must last a month or longer and must be associated with significant disturbance or distress in work, family, or social functioning. Chronic PTSD is diagnosed if these symptoms persist for 3 mo or longer. Delayed onset PTSD refers to symptoms developing at least 6 mo after the event. If a person develops similar symptoms within a month after the traumatic event, acute stress disorder (ASD) may be diagnosed. ASD requires three to five dissociative symptoms, one or more of each of the re-experiencing, avoidance, and hyperarousal symptoms, as well as functional impairment. ASD is associated with increased risk to later develop PTSD, though PTSD does not necessarily follow ASD.

PREVALENCE AND RISKS Epidemiological studies in the United States, including the National Comorbidity Study, report that up to 90% of Americans experience a traumatic event in their lifetime. Events reported include life-threatening accidents, natural disasters, combat, rape, physical attacks, child abuse, witnessing the death or injury of another person, and traumatic loss of a loved one. With a lifetime prevalence of about 10% in women and 5% in men, PTSD is among the most common psychiatric disorders. The likelihood to develop PTSD in response to a trauma varies considerably depending on the specific type of event experienced. For example, about half of all rape victims develop PTSD compared with 14% of individuals who suddenly lose a loved one, 7.5% of accident victims, and 2% of individuals who learn about a trauma.

Based on the lifetime prevalence rates, female gender appears to be a risk factor for PTSD. This risk might reflect increased vulnerability of women to the effects of trauma or gender differences in the prevalence of types of events that are more frequently associated with PTSD, or the interaction of both. For example, women more often experience molestation than men and are also more likely to develop PTSD related to molestation. Rape is 10 times more common in women compared with men, but men are more likely than women to develop PTSD in response to being raped. Women, in contrast, are more likely than men to develop PTSD after physical assault, though physical assault is less common in women. Because of the high frequency of these specific traumas experienced by women, or to which women more frequently respond with PTSD, overall lifetime prevalence of PTSD is higher in women than in men.

Because not all women or men who experience traumatic events continue to develop PTSD, additional factors appear to moderate a person's risk to develop PTSD. Factors that increase the risk to develop PTSD include severity and duration of the trauma, proximity to the event, degree of danger, repetition of a trauma, infliction by other people (social trauma, such as rape or molestation), and negative reactions from family and friends. Perceived vulnerability and lack of control are important factors that might increase the risk for later PTSD. In general, events that involve an interpersonal component (e.g., rape, assault, or terrorist attacks) more likely induce PTSD than traumas that are not inflicted by persons (e.g., natural disaster). In addition to these factors that describe characteristics of the traumatic event, characteristics of the person exposed to the trauma also play a role. For example, previous or comorbid psychiatric illness, certain personality disorders, low intelligence, poor coping abilities and other factors increase the likelihood to develop PTSD. As discussed next, a family history of psychiatric illness (especially anxiety disorders and depression) and previous stressful experiences (particularly early in life) further increase individual risk to develop PTSD in response to given events, suggesting that genetic and environmental factors may influence susceptibility to PTSD.

NEUROBIOLOGY Because the development of PTSD by definition is related to extreme stress experiences, changes in neurobiological systems that participate in the mediation of stress responses have been extensively studied in patients with PTSD. One of the key mediators of stress in the central nervous system (CNS) is corticotropin-releasing factor (CRF). CRF neurons and receptors are heterogeneously distributed throughout the brain and are found in brain regions integral to cognitive and emotional processing, as well as autonomic and neuroendocrine regulation. Microinjections of CRF into the CNS of laboratory animals produces integrated endocrine, autonomic and behavioral responses that parallel signs of stress, depression and anxiety, including loss of appetite, sleep disruption, decreased sexual behavior, despair, increased motor activity, neophobia, facilitated fear conditioning, and enhanced startle reactivity. Treatment with CRF receptor antagonists or CRF receptor knockouts exhibit attenuated stress responses. A circuit connecting the amygdala and the hypothalamus with the locus ceruleus, in which CRF and norepinephrine (NE) are the major neurotransmitters, participates in the regulation of vigilance, anxiety and fear, and the integration of endocrine and autonomic responses. Given the pre-eminent role of CRF in mediating stress and anxiety, it is understandable that the hypothesis that PTSD patients exhibit CRF hypersecretion has been promulgated. Indeed, patients with

combat-related PTSD exhibit marked and sustained elevations of CRF concentrations in cerebrospinal fluid (CSF), obtained by a single lumbar puncture or by using an indwelling subarachnoid catheter for collection of CSF over 6 h. PTSD patients also exhibit elevated CSF NE concentrations. Elevated CRF and NE availability plausibly explains many core symptoms of PTSD, such as sleep disruption, increased autonomic arousal, imprinted emotional memories, and enhanced startle reactivity.

CRF neurons in the hypothalamic paraventricular nucleus (PVN) form the CNS component of the hypothalamic-pituitary-adrenal (HPA) axis, the major stress system in mammals. When exposed to stress, CRF is secreted from nerve terminals in the median eminence into the hypothalamus–hypophyseal portal circulation and activates CRF receptors on corticotrophs stimulating the production and release of adrenocorticotropic hormone from the anterior pituitary. Adrenocorticotropic hormone in turn stimulates release of glucocorticoids (cortisol in humans) from the adrenal cortex. Glucocorticoids exert marked effects on metabolism, immune function and the CNS. Cortisol secretion is essential for successful adaptation of the organism to stress. Although there is evidence for hyperactivity of CNS CRF systems in PTSD, paradoxically, basal cortisol secretion appears to be reduced in PTSD patients compared with healthy volunteers, though this finding has not been consistently replicated. However, even normal cortisol output reported in some studies for PTSD patients is inappropriately low in the face of elevated CRF secretion. Low basal cortisol secretion may reflect increased negative feedback sensitivity of the HPA axis, though mild adrenal insufficiency might also play a role. Low cortisol secretion in PTSD might represent a counter-regulatory adaptation to central hyperactivity. Cortisol is also known to inhibit the NE-CRF feedforward loop in the brain. Therefore, perhaps reduced cortisol availability (as a consequence of genetic disposition or prior experience) before a given trauma and/or too rapid shutdown of the peripheral cortisol response might represent risk factors leading toward disinhibition and perpetuation of CNS responses to stress, which might ultimately evolve into PTSD symptoms. Indeed, increased endocrine responses to laboratory stress and imagery of the trauma have been documented in PTSD patients.

Several brain pathways modulate HPA axis activity. The hippocampus and the prefrontal cortex inhibit the HPA axis, whereas the amygdala and monoaminergic input from the brainstem stimulate PVN CRF neurons. Sustained excessive glucocorticoid exposure is known to produce adverse effects on hippocampal neurons, including reduction in dendritic branching, loss of dendritic spines, and impairment of neurogenesis. Glucocorticoids also adversely affect the prefrontal cortex. Although basal plasma cortisol concentrations are low in PTSD, relatively small hippocampal volumes are seen in patients with PTSD. Functional neuroimaging studies provide evidence for altered activity of the hippocampus, which is likely related to cognitive deficits in PTSD. These structural changes could be secondary to increased cortisol secretion at the time of the trauma or in response to repeated stresses, or they could reflect a pre-existing vulnerability marker for the development of PTSD. Other studies document decreased activity in frontal cortical regions and increased amygdala responses to traumatic or emotional stimuli in PTSD patients.

OTHER TRAUMA SPECTRUM DISORDERS

Experiences of extreme stress or trauma are also associated with several disorders other than PTSD, including depression, other anxiety disorders, alcoholism, substance abuse, personality disorders, and somatoform disorders. Trauma exposure not an essential diagnostic requirement in these disorders, and these disorders often occur in individuals who did not experience a major trauma. However, stress and trauma dramatically increase an individual's risk to develop these disorders, particularly when experienced early in life. Episodes of these disorders are often precipitated by stressful life events in adulthood. A complex interplay between stresses across the life span, coupled with genetic vulnerabilities and other risk factors, is thought to underlie these disorders' manifestation.

Trauma spectrum disorders, including PTSD and the previously mentioned disorders, often occur together in one individual. For example, the National Comorbidity Study reports that lifetime comorbidity rates of PTSD patients are 49% for major depression, 40% for alcohol abuse, 31% for drug abuse, 28% for social phobia, 16% for generalized anxiety disorder, and 10% for panic disorder. About half of individuals with a lifetime history of PTSD have three or more comorbid additional Axis I disorders. In trauma survivors, PTSD often precedes the onset of mood and alcohol abuse disorders. In Axis II disorders show a high comorbidity rate between BPD and PTSD, prompting suggestions that BPD might represent a chronic form of PTSD. However, because almost half of patients with BPD do not have a lifetime history of PTSD, it appears that BPD is more closely related to trauma experience itself rather than PTSD, though many patients with BPD do not have any trauma history. Many patients with PTSD and other trauma spectrum disorders also have multiple somatic symptoms, including chronic pain symptoms, which also appear to be associated with traumatic experiences. These findings lend substantial support to the concept of trauma spectrum disorders. Certain personality traits, such as neuroticism, are risk factors for many of these disorders. Substantial support for the existence of a spectrum of trauma-related disorders, which likely share the same common pathophysiology, has emerged.

Are there neurobiological similarities among the various trauma spectrum disorders and PTSD? All trauma spectrum disorders have been associated with HPA axis alterations, though the nature of the alterations varies in the different disorders. Thus, severe major depression, for example, melancholia, has been associated with increased cortisol output and HPA feedback resistance, opposing the findings in PTSD. Despite these discrepancies, depression and PTSD share many CNS alterations, including increased CRF and NE activity, smaller than normal hippocampus volumes, and functional alterations in limbic and prefrontal cortical areas. Other trauma spectrum disorders, such as BPD and chronic pain syndromes, have been associated with low cortisol levels and increased HPA feedback sensitivity, similar to the findings in PTSD. Basal cortisol output may be decreased in nonpsychotic depression, particularly if the depression is associated with trauma and PTSD. These examples demonstrate considerable overlap in the neurobiological alterations of several trauma-related disorders. These overlapping pathophysiologies might reflect effects of trauma and/or neurobiological correlates of symptoms, which overlap among these disorders. Alternatively these commonalities might reflect underlying stress vulnerability, which might confer risk to develop an array of symptoms and syndromes on trauma exposure. Inherent stress vulnerability is likely the result of a complex interplay of genetic factors, experiences and other factors.

PROBLEMS IN STUDYING THE GENETICS OF TRAUMA SPECTRUM DISORDERS

Because trauma spectrum disorders are complex behavioral disorders, many factors complicate studies on underlying genetic

vulnerability. One major problem is that an epigenetic factor in the form of a severely stressful event is required to "uncover" the susceptibility to trauma spectrum disorders and, for PTSD, to develop or be diagnosed with the disorder. Following is an overview on these problems using PTSD as the prototype. Genetic vulnerability for PTSD, like those for other major psychiatric disorders (schizophrenia, depression, and bipolar disorder) is likely not determined by a single gene inherited in a Mendelian pattern. High rates of comorbidity between PTSD and other (trauma spectrum) disorders, variability of symptoms within the PTSD category, and multiple psychopathologies in family members of patients with PTSD are consistent with a complex mode of inheritance. Thus, several genes likely "collaborate" in defining the vulnerability and the phenotype, and different genes may contribute to the same phenotype. The latter phenomenon is referred to as "genetic heterogeneity."

The development and diagnosis of PTSD, in contrast to other trauma spectrum disorders, depends on a trauma exposure. Because not all individuals in the population experience a trauma capable of inducing PTSD, not all individuals can or will be diagnosed with PTSD, even if they carry high genetic risk. Thus, even if an individual is at high genetic risk for PTSD, the disorder might actually never develop because the traumatic triggering event never occurs. This is referred to as "incomplete penetrance," which considerably complicates research on the genetics of PTSD.

The phenotype definition of PTSD according to DSM-IV is also problematic for genetic research. For example, the dichotomous categorization of whether an individual has PTSD or does not have PTSD is highly arbitrary and leads to a loss of information. This is also true for categorical distinctions between PTSD and other trauma-spectrum disorders. DSM-IV criteria are not designed to minimize false-positives, and are unrelated to specific pathophysiological mechanisms. There is as yet no marker of genetic risk for PTSD to detect vulnerable patients who never experienced a trauma.

Especially pertinent for trauma spectrum disorders are observations that genes for psychiatric disorders may be pleiotropic; the same gene contributes to the manifestation of several different disorders. The facts that PTSD patients have extremely high rates of comorbid psychiatric disorders and that certain psychiatric disorders are over represented among the relatives of patients with PTSD, are consistent with the presence of a pleiotropic gene. Such a pleiotropic gene may underlie genetic vulnerability for a "core" disorder common to the spectrum of disorders that are manifested after exposure to stress and trauma. Additional genes might modify this phenotype, leading to specific clinical expressions categorized as separate disorders in DSM-IV.

Considerable evidence exists that the risk to develop PTSD or other trauma spectrum disorders increases with the severity of trauma. This suggests that the genetic risk for PTSD is particularly important at the lower end of the trauma severity continuum, whereas toward the higher end of the severity continuum, individuals without any genetic risk might develop the disorder. Thus, it is possible that some persons develop PTSD or another trauma spectrum disorder following very severe traumas without any significant genetic contribution. Moreover, resilience and the possible existence of resilience genes may contribute to invulnerability to PTSD development. It is also likely that the impact of an environmental event on a specific disease is moderated by age at the time of the event, type of the event or pre-existing disorders. Genetic research on trauma spectrum disorders, including PTSD, is complicated by the circumstance that some types of exposure, such as child abuse or going to war, are heavily influenced by genetic dispositions or certain personality traits that are in turn genetically influenced.

GENETICS OF TRAUMA SPECTRUM DISORDERS

FAMILY STUDIES Family studies have been used to elucidate the potential genetic contributions to PTSD and other trauma spectrum disorders. The first family studies on PTSD-like symptoms were performed after World Wars I and II. Remarkably, these studies found that immediate relatives of soldiers, who suffered from PTSD-like symptoms, more often had psychiatric problems, such as "insanity," nervousness, alcohol abuse, and neurasthenia. Familial aggregation of PTSD and the prevalence of other psychiatric disorders in family members of PTSD patients have been examined. For example, the offspring of a parent with PTSD has a fivefold increased risk of PTSD development. The risk of developing PTSD is two- to threefold higher if a family member suffers from depression, an anxiety disorder other than PTSD, or a personality disorder. A family history of alcohol or substance abuse, surprisingly, was not found to be associated with an increased risk for PTSD, though an increased prevalence rate of these disorders was found in siblings of patients with chronic PTSD.

Similar patterns of familial aggregation are also found among trauma spectrum disorders other than PTSD. For example, familial aggregation and transmission of BPD has been reported, but so has only a familial relationship for individuals who had BPD and comorbid depression. It is assumed that, when all family studies are combined, the morbid risk of BPD in first-degree relatives is 11.5%. There is also a suggestion that BPD has a familial relationship to alcoholism and substance abuse. Interestingly, relatives of BPD patients show increased rates of impulsive or affective personality traits, suggesting that familial relationship might be stronger for dimensions such as impulsiveness/aggression and affective instability than for the diagnostic entities. In sum, it appears that a cluster of disorders and traits run in families. This cluster resembles the spectrum of trauma-related disorders, and also seems to include traits that are risk factors for them.

These and other findings from family studies suggest a genetic susceptibility for PTSD and other trauma spectrum disorders. However, family studies are difficult to interpret because it is uncertain whether the aggregation observed is resulting from genetic factors, other biological factors, or shared experience. The association of familial psychopathology and PTSD may be mediated by increased risk of traumatic exposure and by pre-existing psychopathology. More valid approaches to detect genetic contributions to trauma spectrum disorders involve studies in twin populations.

TWIN STUDIES Several twin studies provide considerable evidence of a hereditary predisposition for PTSD. The first substantial data on PTSD in twins were results from the Vietnam Era Twin Registry project, which included more than 4000 male–male pairs of Vietnam Era veteran twins. When adjusting for variance in the heritability of trauma exposure, it was estimated that genetic factors accounted for approx 30% of the variance in liability for most of the PTSD symptoms in all symptom clusters (intrusion: 13–30%; avoidance: 30–34%; hyperarousal: 28–32%). Interestingly, shared family environment, such as parental style among others, did not contribute to susceptibility to PTSD. The remaining variance was resulting from nonshared,

unique environmental experiences. Because this study recruited solely male twins and focused exclusively on the trauma of combat exposure, the findings cannot be generalized to women and other types of trauma. Twins in another study of 406 male and female twin pairs from the general population in Canada did not experience combat trauma, but an array of civilian traumas, including robbery, assaults, violent family death, accidents, fire, and natural disasters. This study confirmed a moderate heritable component for the development of PTSD symptoms and, again, the remaining variance was accounted for by unique environmental experiences.

As for trauma spectrum disorders other than PTSD, twin studies show that 40–50% of the risk to develop depression is genetic, even higher for bipolar disorder. Other anxiety disorders have somewhat less of a genetic component, but it is substantial. Alcohol and substance abuse disorders are moderately heritable (for genetics of these disorders, *see* Chapter 129). There is also evidence for a genetic component in the development of BPD. In a Norwegian twin study of 221 twin pairs, about 60% of the BPD liability was genetic and about 10% was resulting from common environmental experiences. If replicated, this would suggest that BPD is a highly heritable disorder. Interestingly, using the twin approach, several studies determined to what extent genetic contributions overlap between PTSD and other disorders that often co-occur in trauma survivors, such as alcoholism, drug dependence, or other anxiety disorders. For example, one study made up of a small number of subjects found that PTSD was only present in cotwins of twins with anxiety disorders, and was twice as prevalent in monozygotic twins compared with dizygotic twins. In another study using the Vietnam Era Twin Registry, the liability for PTSD was partially resulting from a 15.3% genetic contribution common to alcoholism and drug dependence and a 20% genetic contribution specific to PTSD. The genetic risk for alcoholism or drug dependence were the same genetic contributions common to PTSD and drug dependence, or PTSD and alcoholism, respectively, as well as specific risk for each disorder. Shared environment contributed to risk for drug abuse. Similar associations were found for genetic overlap between PTSD, generalized anxiety disorder and panic disorder. Another study evaluating twin pairs discordant for combat exposure found that monozygotic combat-unexposed cotwins of subjects with PTSD had significantly more symptoms of mood disorders than monozygotic cotwins of combat controls, suggesting that genetic vulnerability contributes to the association between PTSD and depression or dysthymia. These studies suggest that there is overlap in genetic predisposition to develop a spectrum of disorders and that each of these disorders also has some specific genetic liability. These findings are not discordant with the concept of trauma spectrum disorders.

MOLECULAR GENETIC STUDIES Although there is evidence from family and twin studies for an inherited vulnerability to develop trauma spectrum disorders in response to severe stress exposure, little is known about the molecular bases of this vulnerability. Although there are no linkage studies in PTSD, most of the small number of association studies in PTSD focused on variations of genes that are involved in dopamine (DA) neurotransmission. The rationale for studying genetic variations in DA systems is based on previous findings that PTSD patients, and stressed animals, show increased DA neuronal reactivity and that stress-induced alterations of brain DA reactivity are at least in part genetically determined. Comparison of 37 drug-dependent Vietnam veterans with PTSD with 19 drug-dependent veterans without PTSD showed that the A1 allele of the DA-2 receptor was more common in those with PTSD. These results suggested that a variant in the DA receptor gene might confer an increased risk for PTSD, whereas the absence of the variant might confer resistance. However, another study failed to replicate these findings. These conflicting results are likely resulting from small sample sizes and the presence of substance dependence in the first study, which might also be associated with the A1 allele. In the second study, trauma exposure was not controlled for in the non-PTSD group. This might have resulted in the inclusion of subjects in the control group with inherited vulnerability to PTSD, which was not expressed because of lack of trauma exposure. Based on these findings, a gene coding for the DA transporter (DAT) was investigated that is located on the nerve terminals of DA neurons, except prefrontal cortical DA neurons. The DAT is responsible for the presynaptic reuptake of DA released into the synaptic cleft, thereby controlling the availability of DA in the synapse to activate postsynaptic DA receptors. A common mutation in the DAT gene was more frequent in trauma survivors who developed chronic PTSD compared with trauma survivors who did not. These findings suggest that a genetically determined variation in DA neurotransmission may participate in shaping pathological responses to trauma, and, in general, vulnerability to the effects of stress. Future studies should also evaluate genetic polymorphisms in critical components of other neural systems that are implicated in stress responses, such as the CRF systems (CRF, CRF receptor subtypes, CRF binding protein), and their role in conferring risk for PTSD. They should also attempt to elucidate a potential molecular basis of the common comorbidity among the spectrum of trauma-related disorders. Interestingly, one study showed that a polymorphism of the γ-amino butyric $acid_A$ receptor β 3-subunit gene is associated with comorbid somatic symptoms and depression among PTSD patients.

GENETICS OF THE BIOLOGICAL FOUNDATIONS OF TRAUMA SPECTRUM DISORDERS

It has become increasingly clear that the classification of psychiatric disorders on the basis of symptomatic phenotypes is not ideal for genetic research trying to dissect vulnerabilities for these disorders. This is particularly true for PTSD and other trauma spectrum disorders mainly because of the wide range of the symptomatic phenotypes and the incomplete penetrance of the phenotype depending on the occurrence of a triggering event, which might in turn be genetically influenced. Therefore, it might be more fruitful for genetic research to focus on internal changes or biological markers that are associated with a given disorder. Such internal biological states are also referred to as "endophenotypes." Although these biological traits might be correlates or consequences of the disease, there may also be preexisting biological vulnerabilities that confer risk to develop a disorder, if trauma occurs. Such underlying biological vulnerabilities might be genetic in nature, be shaped by the person's environment, or both. With advances in detecting biological underpinnings of PTSD and other trauma spectrum disorders, there are exciting possibilities to explore the genetics of the neurobiological mechanisms involved in pathological stress responses, such as deficits in hippocampal structure, fear responses, and sensitization of CRF systems.

HIPPOCAMPUS SIZE LINKED TO PATHOLOGICAL VULNERABILITY TO TRAUMA Preclinical studies show that stress can damage the brain, particularly the hippocampus. The

hippocampus is a brain structure important for declarative memory, contextual aspects of fear conditioning and control of the HPA axis. Overexposure of the hippocampus to high concentrations of glucocorticoids during states of ongoing stress is thought to lead to atrophy and neuronal loss in the hippocampus, which in turn contributes to the symptoms of stress-related disorders. In fact, structural MRI shows the hippocampus to be smaller in patients with PTSD compared with controls. Similar findings exist in patients with major depression. The size of the hippocampus in PTSD has been a "chicken-or-egg" question. Whether this region shrinks as a result of the trauma exposure (and presumed HPA axis activation) or because of the presence of PTSD itself, or whether it might already be smaller before a person undergoes a traumatic event has been debated. The latter suggests that a small hippocampus is a risk factor for PTSD. Researchers have been able to address this question using a twin study design of 40 pairs of identical twins, including Vietnam veterans who were exposed to combat trauma and their cotwins who did not go to Vietnam, by measuring the size of the hippocampus in all the twins. As expected, among Vietnam veterans, the hippocampus was smaller in those with PTSD compared with those who did not develop the disorder. However, this brain region was also smaller in the cotwins of the men with PTSD, suggesting that a smaller hippocampus is a preexisting, potentially genetic, vulnerability factor that predisposes to PTSD and other trauma spectrum disorders, after exposure to stress or trauma.

A GENE BIASES THE AMYGDALA TO OVER-REACT TO FRIGHTENING FACES Functional brain imaging has provided compelling evidence of a strong genetic component to the extent to which the amygdala reacts to emotional stimuli. The amygdala is a limbic brain structure integral to fear responses. Its response to pictures of frightening faces depends on which form of a gene involved in serotonergic neurotransmission is present. Subjects who had one or two copies of the short variant of the human serotonin transporter (SERT) gene, associated with reduced serotonergic transmission, showed greater activation of the amygdala to fearful faces compared with those who had two copies of the long variant of the gene. In previous studies, variations of this gene have been associated with increased trait-like anxiety and heightened stress reactivity. Thus, this gene might be associated with a phenotype with particular vulnerability to pathological responses to stress, which might promote the development of emotional disorders, if trauma occurs.

"JUMPINESS" AS AN INHERITED VULNERABILITY MARKER FOR PTSD Exaggerated startle reactivity is one of the diagnostic criteria for PTSD. PTSD patients exhibit greater than normal physiological reactions, such as eye-blink, heart pounding and sweating, when exposed to loud or sudden tones, or to unexpected touch. The startle response is a reflex common to all mammals. Interestingly, the amplitude of the startle reflex can be modulated by the induction of emotional states. In the context of fear, the startle reflex is enhanced. In contrast, twin studies revealed high rates of concordance in startle reactivity among healthy identical twins in general. Based on the previously mentioned and similar to discussions regarding the origin of a small hippocampus in PTSD, it has been debated whether an exaggerated startle reactivity might be a consequence of trauma exposure or a correlate of having PTSD, or whether it might be a pre-existing vulnerability factor that increases the risk of a person to develop PTSD on trauma exposure. A study in identical twin pairs discordant for Vietnam combat exposure helped address this question. Combat-exposed Vietnam veterans with PTSD showed exaggerated responses to loud and sudden tones. However, their nonexposed cotwins showed responses similar to combat veterans without PTSD and their nonexposed cotwins. These results strongly suggest that increased startle reactivity is secondary to PTSD rather than a preexisting vulnerability trait.

HIGHER THAN NORMAL STRESS HORMONE RESPONSES IN FAMILIES Stress activates the HPA axis, which is mainly controlled by hypothalamic CRF. Increased activation of CRF and sensitization of the HPA axis have been measured in patients with in PTSD and other stress-related disorders. The behavioral effects of CRF at extrahypothalamic sites, together with the manifold effects of cortisol on the brain, are thought to underlie many of the symptoms of trauma spectrum disorders, including anxiety and depression. Although severe and ongoing stress can markedly alter the activity of CRF neurons and the dynamics of the HPA axis, less is known about the extent to which CRF and HPA axis function are shaped by genetics. Heightened reactivity of CRF systems and the HPA axis to a given stressor or trauma might confer increased risk to develop pathological conditions related to stress. A study of first-degree relatives of depressed patients who never suffered from a psychiatric disorder themselves, showed increased cortisol responses to a pharmacological challenge test (the dexamethasone-CRF test) that is highly sensitive to detect HPA axis hyperactivity. Increased reactivity in this test was found to be constant overtime, possibly reflecting an inherited trait, though experiences shared within families might contribute to these results. These findings are complemented by reports from studies in healthy twin pairs that revealed moderate heritability of HPA reactivity to laboratory stress. Inherited neuroendocrine stress reactivity might be based on polymorphisms of genes that participate in the regulation of neuroendocrine stress responses, such as glucocorticoid receptor and CRF receptor genes. Whether inherited neuroendocrine sensitization contributes to the risk for the development of PTSD and other trauma spectrum disorders after trauma exposure is unknown.

INTERACTION OF GENOTYPE AND EXPERIENCES ACROSS THE LIFE SPAN

INFLUENCE OF LIFE EXPERIENCES Trauma spectrum disorders, in particular PTSD, by definition occur in the context of a traumatic experience. Because not everyone exposed to such an experience develops PTSD or a related disorder, the manifestation of these illnesses depends on the interaction of the traumatic experience with dispositions of the person and other situational factors that a person is exposed to surrounding the traumatic experience. Thus, the manifestation of trauma spectrum disorders probably reflects a complex gene by environment interaction. The severity and nature of the index trauma itself plays a major role in determining whether the victim develops PTSD or another disorder. However, experiences other than the index trauma also shape the risk to develop a trauma spectrum disorder. The effects of early developmental experiences on later vulnerability to subsequent stresses and its relationship to the development of psychiatric disorders have been studied. Compelling evidence from epidemiological, twin, and case–control studies suggests that adverse experiences during childhood have pronounced and long-term effects on later stress vulnerability, and represent major risk factors for the development of mood and anxiety disorders in adulthood. There is a complex relationship between early-life stress and PTSD. A traumatic event experienced early in life surely is a

form of early stress, but not all forms of early-life stress are necessarily traumatic events. For example, chronic demands of a young child to manage a family household would not meet the DSM-IV A criterion, but may exert pronounced influences on the child's subsequent vulnerability to stress and PTSD. Thus, the relationship between early-life stress and PTSD can be direct or indirect. In the direct relationship, the early stress experience itself represents the index trauma to which PTSD symptoms are related. Indirect relationships between early-life stress and PTSD occur in at least two ways. Early-life stress increases the risk of later trauma that may, in turn, elicit PTSD and early-life stress also increases the risk for the development of PTSD in response to traumas occurring in adulthood, such as combat. Such sensitization of responses to trauma has been observed after child abuse experiences, but also after more subtle instances of early stress, such as negative parenting style or neglect. In addition, acute or chronic life stresses in adulthood that are not traumatic also exacerbate or aggravate PTSD. Similar relationships exist for other disorders that are often precipitated by stressful events, such as depression.

The pronounced effects of early-life stress on vulnerability to stress and psychopathology are surely mediated by the substantial plasticity of the developing brain as a function of experience. During such critical periods, certain brain regions are particularly sensitive to adverse experiences, which may then lead to major, perhaps irreversible, alterations. Findings from laboratory animal studies have provided direct evidence that stress or trauma during development permanently shapes the structure and function of brain regions involved in the mediation of stress and emotion, leading to altered emotional processing and heightened responsiveness to stress. Adult rats separated from their mothers for brief periods of time in the first 2 wk of life exhibit up to threefold increases in HPA axis responses to mild stressors and develop marked behavioral changes including increased anxiety-like behavior, anhedonia, alcohol preference, sleep disruption, and cognitive impairment. Many of these changes resemble cardinal symptoms of trauma spectrum disorders. Evidence exists that similar changes occur in humans after early-life traumatic events. Thus, women abused as children exhibit greater HPA axis and autonomic responses to a standardized psychosocial laboratory stress, the Trier Social Stress Test, compared with controls, and the increase is more pronounced in those abused women with current depression. Taken together, these and other findings from the developmental neurosciences strongly suggest that endophenotypes, which underlie manifestations of psychiatric disorders, do not necessarily reflect genetic variations influencing the blueprint of the brain, but that the structure and function of the brain is profoundly shaped by experiences throughout development, which is then expressed into behaviors.

INTERACTION OF GENES AND ENVIRONMENT Not all individuals exposed to trauma develop a trauma spectrum disorder. Similarly, not every child who experiences adverse life events, such as abuse, neglect or loss, will be sensitized to stress and or develop certain stress- or trauma-related disorders, even on further stress challenge. In addition to protective environmental and psychological factors, genetic vulnerability and resiliency factors must be considered. For instance, the risk to develop PTSD in response to combat exposure is moderated by the presence or absence of polymorphisms in genes involved in DA neurotransmission. Such genetic moderation might also occur related to the effects of early-life stress on later stress vulnerability/resistance and risk/resilience for stress-related disorders. One study provided particular insight. A prospective-longitudinal study of a representative birth cohort sought to determine why stressful experiences lead to depression in some individuals but not in others by evaluating the presence or absence of the functional polymorphism in the promoter region of the SERT. This polymorphism moderates the influence of stressful life events on depression. Individuals with one or two copies of the short allele of the SERT promoter exhibited more depressive symptoms, diagnosable depression, and suicidality in relation to stressful life events, including child maltreatment, than individuals homozygous for the long allele. As noted, individuals with the same genetic variation also exhibited traits of anxiety, heightened stress reactivity, and increased amygdala responses to frightening faces. Thus, the gene-by-environment interaction in this epidemiological study likely reflects genetic moderation of the brain's functional response to stress, including child maltreatment, which translates into psychiatric symptoms. Similarly, the same investigators studied a large sample of male children from birth to adulthood to determine why some maltreated children grow up to develop antisocial behavior, whereas others do not. In that study, a functional polymorphism in the gene coding for the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAO-A) moderated the effects of maltreatment. Maltreated children with a genotype conferring high levels of MAO-A expression were less likely to develop antisocial disorder.

IS EXPOSURE TO TRAUMA GENETICALLY DETERMINED? Two twin studies provided evidence that exposure to trauma is moderately heritable. For example, it was shown in the Vietnam era Twin Registry project that genetic factors accounted for 36% of the variance in volunteering for service and 47% of the variance in combat exposure. In the Canadian PTSD twin study, similar heritability rates were found for exposure to assaultive traumas, but not nonassaultive traumas. There is also evidence that, in addition to trauma, exposure to any type of stressful life events is influenced by genetic factors. Findings from several twin populations suggest that exposure to childhood maltreatment, abuse or parental loss is, in part, genetic. For example, data obtained from the Virginia Twin Registry reflects that 20–30% of the variance in the exposure to a disturbed family environment, sexual abuse, or parental loss is explained by genetic loading for depression. These relationships might be explained by the genotype of the parents or the child. Parents of twins with depression would have high liability to major depression, which would likely predispose directly to family discord and divorce. Also, childhood temperament, influenced by genetic factors, could contribute to familial discord, abuse, and loss. It indeed appears that persons with high genetic risk for depression self-select into stressful environments, which in turn increases the risk for depression. A major challenge for future studies will be the task of separating genetic heritability factors for stress or trauma exposure from heritability factors for developing symptoms in response to these insults, and to elucidate the underlying neurobiological mechanisms.

CLINICAL IMPLICATIONS

Trauma spectrum disorders are complex disorders related to the experience of severe stress. The concatenation of findings strongly supports a developmental model that combines genetic and environmental factors across the life span to explain individual risk and resilience of developing adult psychopathology in response to a trauma. Despite the inherent difficulties of studying

the genetics of trauma-related disorders, the field has exhibited remarkable advances. Particularly exciting are those of the genetic and environmental contributions to functional brain mechanisms that underlie the symptoms of trauma spectrum disorders. With the identification of polymorphisms in critical genes that influence the availability of certain neurotransmitters involved in the stress response, a rapid increase in knowledge on the nature of gene-by-environment interactions that determine whether an individual will develop a disorder in response to trauma has occurred. Rapid advances in the discovery of the precise genetic contributions to environmental or trauma-related disorders are anticipated. Discovery of the genetic bases of trauma spectrum disorders will aid in accurate diagnosis of persons at risk, even before trauma exposure. Such strategies will allow for effective prevention and, if trauma occurs, for direct treatment of pathological responses based on an accurate understanding of the biological pathways implicated in the "core trauma disorder" and the cognate trauma spectrum disorders. Some of the polymorphisms that confer risk to develop disorders in response to trauma may even be amenable to gene therapy.

128 Schizophrenia

CAROL A. TAMMINGA, DEBORAH C. MEDOFF, AND GUNVANT THAKER

SUMMARY

Despite a broad knowledge base about the pathology of schizophrenia, albeit fragmented and often inconsistent, no theme has emerged to link the illness with its molecular pathophysiology. There is insufficient certainty and consistency of findings to identify the critical molecular target on which to base therapeutic discovery. The most limiting aspect of schizophrenia therapeutics is this lack of critical knowledge with respect to its target pathophysiology, on which therapeutic strategies could be developed.

Key Words: Central nervous system; electroencephalographic; homovanillic acid; magnetic resonance imaging; regional cerebral blood flow; schizophrenia.

INTRODUCTION

The molecular pathology of any disease might be nowhere more obscure than in schizophrenia. Observations have been made about disease manifestations, illness course, risk factors, genetics, postmortem tissue characteristics, and clinical pharmacology. Despite this broad knowledge base, albeit fragmented and often inconsistent, no theme has emerged to link the illness with its molecular pathophysiology. There is insufficient certainty and consistency of findings to identify the critical molecular target on, which to base therapeutic discovery. The most limiting aspect of schizophrenia therapeutics is this lack of critical knowledge with respect to its target pathophysiology, on which therapeutic strategies could be developed. Nonetheless, several experimental frameworks have been proposed to explain the illness.

SYMPTOMS Symptom manifestations of schizophrenia are well established: hallucinations, delusions, and/or thought disorders (positive symptoms), sometimes in a context of negative symptoms (anhedonia, asociality, and alogia), and often of cognitive dysfunction (especially, attention working memory and executive function failure). Many symptom surveys of large populations of persons with schizophrenia confirm that positive symptoms, negative symptoms, and cognitive dysfunction clusters run together during the disease course and in response to pharmacological agents. Although positive symptoms are often, though not inevitably, extensively treated with current antipsychotics, negative and cognitive dysfunctions are not robustly responsive to these medicines. Persons early in their course of illness, especially first-break individuals, show the greatest therapeutic response to medication with the robustness of therapeutic response decreasing with disease duration.

Symptoms, particularly positive symptoms, can be provoked or exacerbated with selected pharmacological probes. Ketamine exacerbates existing psychotic symptoms in volunteers with schizophrenia, and produces mild psychotomimetic symptoms in controls (some would say schizophrenia-like symptoms). Amphetamine can induce discrete paranoid psychotic states after repeated administration in controls, but fails to exacerbate psychosis in schizophrenia.

Certain brain regions have been associated with symptom manifestations in schizophrenia using in vivo imaging techniques. Correlation exists of the parahippocampal gyrus and ventral striation with positive symptoms. Correlation between active hallucinations and the thalamus, parahippocampal gyrus, and anterior cingulate cortex (ACC) in actively psychotic persons has been shown. Significant correlation exists between positive symptoms and limbic regional cerebral blood flow (rCBF) in drug-free persons with schizophrenia. Neuronal hypoactivity occurs in the dorsolateral prefrontal cortex and superior parietal cortex associated with negative symptoms.

COURSE Schizophrenia is characteristically associated with a life-long course of psychotic illness. Occasionally, and in the best of outcomes, the illness is of fast onset, episodic in nature, with symptoms first occurring in early adult years, and showing good recovery between episodes. More often, other patterns of illness occur, including an insidious onset, partial recovery, or perhaps even a remarkable lack of recovery between episodes. In most persons with schizophrenia, a profound deterioration occurs in mental and social function in the first years of illness. After this initial deteriorating phase, the further course of illness can settle at a lower, but stable symptom plateau. Surprisingly symptoms can improve in later life. The Vermont study found considerable heterogeneity in outcome in later life among schizophrenics, including some frank late improvers. Specifically, more than half of the 269 patients (with a 97% follow-up rate) had no psychotic symptoms after 10 yr of study (after about 15–20 yr of illness), and most had a "good" level of function in their later life. These data are consistent with several other outcome studies in Europe and the United States that report frequent good outcome in later years for individuals with schizophrenia. No data are available to distinguish between the two possibilities that elder years are merely less demanding periods for mental performance or that the normal aging process is therapeutic in the illness. That the disease course can be flat in its middle years distinguishes schizophrenia from

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

traditional neurodegenerative disorders where the course is progressively downhill (like Parkinson's disease or Alzheimer's dementia) and from traditional neurodevelopmental disorders (like mental retardation) where course is steady and low from the beginning of life.

RISK FACTORS The evidence that schizophrenia aggregates in families is clear and consistent. First degree relatives of schizophrenic probands have a lifetime risk of 3–7% of manifesting schizophrenia compared with a 0.5–1% lifetime risk of relatives of control individuals. Twin studies have identified the familial factor as a genetic rather than an environmental risk. The monozygotic twin of a schizophrenic has a 31–78% chance of eventually developing the illness compared with a 0–28% risk for a dizygotic twin. The genetic mechanism of transmission has not been defined despite significant efforts in both association and linkage studies; it will inevitably be a complex genetic inheritance.

The proposal that pregnancy and birth complications are associated with schizophrenia has been extensively studied and is generally widely accepted. The overall effect when calculated is small, increasing risk of disease by approx 1–2%. Perinatal insults include low birthweight, prematurity, pre-eclampsia, prolonged labor, hypoxia, and fetal distress. That these insults occurring at birth could be associated with an onset of schizophrenia 20 yr later implies the possibility of a causal connection between perinatal accidents and the illness. The hypothesis that anoxic damage to pyramidal cerebral neurons in the hippocampus could mediate an increased schizophrenia risk is plausible. Of course, most schizophrenic persons do not have a positive history for these early birth insults; neither do most persons who suffer such early birth trauma develop schizophrenia.

A repeatedly reported epidemiological characteristic of schizophrenia is the excess of winter births over spring births. The effect is small but highly replicable. Despite the consistency of the finding, the reason for the association remains obscure. Seasonal variations in birth complications, temperature, life style, diet, and in rates of infections have been suggested. It is tempting to suggest that a warm weather infective organism is causally involved in predisposing the young summer fetus (which will ultimately become the winter born infant) to the illness. Although this remains a possibility, direct evidence to support any causal association is lacking. Until found, the excess of schizophrenia with winter births is a rather firm observation in search of a proper explanation.

BRAIN STRUCTURE

The application of magnetic resonance imaging (MRI) to the study of brain structure in schizophrenia has distinguished schizophrenia from other brain diseases. MRI requires meticulous clinical technique and attention to the many sources of imaging artifact. Early MRI studies reported a decrease in brain size, an increase in ventricular volume, and variable cortical wasting in schizophrenia, confirming and extending literature describing the CT examination of schizophrenia that showed the same findings with the cruder CT technique. MRI techniques have found a volume decrease in the medial temporal cortex structures, hippocampus, amygdala, and parahippocampal gyrus, especially in studies with dense volumetric sampling. Moreover, techniques for shape analysis of the hippocampus have revealed striking regional differences of the hippocampus in schizophrenia. Not only is the volume of the superior temporal gyrus reduced, but the magnitude of the reduction appears related to the presence of hallucinations and to electrophysiological changes in patients. Reports of structural changes in other brain regions assessed by MRI have been less consistent but interesting. Increases in sulcal size, decreases in grey matter volume, and altered gyral patterns have been found. White matter increases in volume have been shown, regionally specific. Neocortical volume reduction might be present in only some symptomatic subgroups of schizophrenic subjects, for example, middle frontal cortex volume reduction in negative symptom schizophrenia. A reduced thalamic volume in schizophrenia has been reported, particularly in the posterior portion, which should direct future interest to this structure. The extent to which the overall volume of a brain structure reflects an internal pathology, especially if the pathology is subtle, is likely limited. Although positive MRI data can identify a brain area for further study, negative results do not rule out areas as pathological; moreover, MRI as a technique does not provide critical knowledge to answer functional relevance. There is always the question of which, if any of these structure changes might be associated with chronic drug treatment rather than the illness. Thus it is important to follow the identification of structural abnormalities with studies to define the associated functional, pharmacological, or electrophysiological techniques.

TISSUE PATHOLOGY

Microscopic analysis of postmortem central nervous system (CNS) tissue is performed to answer whether a systematic neuropathological lesion exists in schizophrenia that could provide a clue to pathophysiology. No obvious, gross neuropathological lesion is present in schizophrenia as occurs in Parkinson's disease or Alzheimer's dementia. Certainly more subtle pathology (if any) must be expected. Considerable resurgence of interest in neuropathological characteristics of schizophrenic brain has occurred. In reviewing schizophrenia neuropathological studies, careful attention is essential to the possible confounds of tissue artifact, chronic neuroleptic treatment, lifelong-altered mental state, and relevant demographic factors.

The wide application of postmortem studies of pathology in schizophrenia tissue in the face of incomplete guiding hypotheses has resulted in broad and fragmented postmortem literature. One modestly consistent observation is a common localization for illness pathology in limbic cortex, but not necessarily a common neuropathological feature. The primary brain limbic structures are hippocampus, cingulate cortex, anterior thalamus, and mammillary bodies and these are associated with other cortical areas like entorhinal cortex that regularly display pathological abnormalities. There are abnormalities of cell size, cell number, area, neuronal organization, and gross structure. The entorhinal cortex shows abnormalities of cellular organization in Layer II neurons. Both structural changes on MRI and (described later) functional changes in PET have targeted these same areas for interest in schizophrenia pathophysiology. The consistency of this localizing pathology, despite the variety of concrete findings, is informative across technically different studies.

Limbic structures are not the only regions that appear to be affected in the postmortem schizophrenic brain. The neocortex, especially frontal areas, have been productively studied with reports of cell or tissue loss; one study reported gray matter volume reductions, two did not, and one reported increased neuronal packing in frontal cortex. The thalamus, based on its pivotal position in relationship to afferent sensory information and as a node for cortical–subcortical circuits, has been studied with inconsistent, but

not negative results. Cell loss and reduced tissue volume in thalamus has been inconsistently reported. Additional studies in frontal cortex and thalamus are needed before firm conclusions can be reached.

The interesting neuropathological finding of basal ganglia enlargement in schizophrenia (in both caudate and putamen) has subsequently been confirmed using in vivo MRI techniques. A small but clear increase exists in caudate and putamen size in neuroleptic-treated schizophrenia cases. That this volume increase occurs only after long-term neuroleptic treatment but not before suggests it is an effect of chronic neuroleptic treatment, not the illness itself. Also, long-term neuroleptic treatment in laboratory rats increases striatal mitochondrial size, increases the size of some axon terminals, and causes a trend toward an increase in the size of dendrites; these findings are consistent with a striatal volume increase with neuroleptic treatment in schizophrenic patients and a good example of a postmortem finding in schizophrenia not associated with the illness but with its treatment.

The idea that a neurodevelopmental insult occurs in the perinatal brain that can predispose to later-onset schizophrenia has received some support from tissue studies in postmortem tissue. A reduction in nicotinamide adenine dinucleotide phosphate diaphorase-staining neurons in the upper layers of the schizophrenic prefrontal cortex and an increase in number (trailing) of these neurons in underlying white matter layers has been reported. These findings are consistent with impairment in neuronal migration of these cells into frontal cortex during their critical developmental period (second trimester) in schizophrenia. Alterations exist in superficial cellular organization (e.g., in Layer II) in entorhinal cortex, with Layer II cell "trailing" in the lower cortical layers, again consistent with a neuronal migratory failure in this area of cortex. Cingulate and middle frontal cortex have greater numbers of neurons present in lower rather than in superficial layers, again consistent with a concept of migratory failure. The early observations of hippocampal neuronal disarray in schizophrenia are consistent with the reported selective loss of two microtubule-associated proteins (MAP_2 and MAP_5) in schizophrenic postmortem hippocampal tissue. The growth-associated protein (GAP)-43 is increased in schizophrenic frontal and lingual gyral tissue. It is a synaptic marker associated with the establishment and remodeling of synaptic connections, which is normally enriched in associational cortex and hippocampus. This finding suggests the possibility of unusual synaptic remodeling in frontal and lingual cortices in schizophrenia and is consistent with altered neuronal activity in these areas, possibly secondary to failed or incomplete neuronal projection systems to, or within, these regions.

Decreased expression of glutamic acid decarboxylase mRNA in schizophrenic prefrontal cortex without significant cell loss has been reported. It is thought that only one of the multiple types of γ-aminobutyric acid (GABA)-containing cortical neurons might be reduced in schizophrenia, the GABAergic chandelier cell. These alterations in GABA system activity may be the basis of the already observed frontal hypometabolism repeatedly reported in functional imaging studies of the illness. In the excitatory glutamatergic system alteration in the composition of the *N*-methyl-D-aspartate (NMDA)-sensitive glutamate receptor in hippocampus has been reported, possibly reflecting the functional disruption of the limbic system.

Although provocative, replication, and extensions of these postmortem findings are critical to confirm the initial results obtained with low subject number and specialized technical procedures. These abnormalities in prefrontal cortex are compelling in schizophrenia because their presence is theoretically consistent with the cognitive changes of the illness.

In biochemical analyses, investigators have found regional increases in dopamine and/or its major metabolite homovanillic acid in postmortem schizophrenic brain tissue. These results are regularly confounded by the ubiquitous use of neuroleptic medication by these patients, even where the analytic techniques are adequate and tissue collection consistent. However, in at least one case, a regional change in homovanillic acid was reported that was not present in other regions and, thus, possibly not caused by neuroleptic treatment owing to its localized nature. Likewise in the measurement of dopamine receptor density, studies regularly report increased $dopamine_2$-family receptor density in schizophrenic caudate and putamen. This receptor upregulation is almost always explained as a consequence of chronic neuroleptic treatment and can be similarly demonstrated in rats, monkeys, and neuroleptic-treated nonschizophrenic humans. Increased $dopamine_4$ density has been reported in schizophrenic caudate and putamen. Because $dopamine_4$ density also increases with chronic neuroleptic treatment, further study of untreated schizophrenic tissue is needed. The comparison of individual $dopamine_2$-family receptor density ($dopamine_2$, $dopamine_3$, $dopamine_4$) in neuroleptic-free schizophrenic tissue with normal control caudate or putamen tissue is being investigated and shows no differences in density of the $dopamine_2$-family subtypes in striatum. $Dopamine_1$-family receptors might be elevated in schizophrenic striatum; this is a small but replicated finding with unknown significance.

On the assumption that transmitter interactions might be important in schizophrenia, one study compared 17 transmitters and their related metabolites in the cerebrospinal fluid of untreated schizophrenic patients with normal controls. No metabolites of dopamine, serotonin, or norepinephrine discriminated groups, but a multivariate analysis of the data set found the combination of tryptophan, tryptophol, and epinephrine distinguished the schizophrenic from the normal group. Although not identifying a specific biochemical lesion in schizophrenia, these results, with reports of kynurenic acid abnormalities in postmortem schizophrenic cortex, focus attention on the potential importance of the kynurenin pathway of tryptophan metabolism in schizophrenia. Biochemical evidence of monoamine involvement in schizophrenia mechanisms is not strong, but the potential involvement of these systems in therapeutics remains an active possibility.

The report of reduced glutamate levels in the spinal fluid of volunteers with schizophrenia suggested hypoglutamatergic neuronal function in the illness. Although this report consistently failed replication, the idea of reduced glutamatergic transmission in schizophrenia has continued to be explored. The demonstration that phencyclidine (PCP) has antiglutamatergic actions, directly supported this idea because PCP is a drug with psychotomimetic properties probably exerted at the NMDA receptor. This demonstration suggested that PCP might have its psychotomimetic properties as a consequence of its antiglutamatergic actions and that perhaps this is the mechanism of endogenous psychosis. This hypothesis continues to be actively explored and broadened.

The density of the glutamate receptors in human postmortem brain tissue has been assessed in schizophrenia. An increase in ^{3}H-kainate binding in the prefrontal cortex has been reported but not in the putamen. An inverse correlation exists between the increased

kainate receptors in prefrontal cortex and glutamic acid concentrations in other brain areas. An increase in kainate and aspartate binding in schizophrenic orbitofrontal cortex and simultaneously a decrease in aspartate binding (putatively a marker for presynaptic reuptake sites) in the left temporal cortex of schizophrenic tissue have been reported. Moreover, also found was an increase in 3H-thienyl-phencyclidine binding (presumably to PCP receptors) in cortex. Decreased expression of non-NMDA receptors in hippocampal CA_3 occurs; consistent with this is a loss of kainate receptors in the hippocampus, without a change in NMDA binding sites. Increased MK801 binding was reported in several schizophrenic brain regions including hippocampus and entorhinal cortex, but not later replicated. NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionate, and kainate receptors in schizophrenic hippocampus were reviewed in four patients without identifying definite group changes.However, striking individual variability was noted, leading to the suggestion of deafferentation of the hippocampus in some schizophrenic subjects. Other studies of NMDA-sensitive receptor subunits suggest the possibility of a change in NMDA receptor composition in schizophrenia, which could alter glutamatergic transmission.

The literature on the involvement of glutamate in schizophrenia is suggestive, but findings have not been consistent in identifying a particular defect. Many assessments for the glutamate system in mammalian brain are imprecise and lack sensitivity and selectivity. Moreover, the understanding of the processes involved in glutamatergic transmission is incomplete. Thus, technical and conceptual issues might be relevant to the failure to replicate findings. Perhaps the variety of disparate hippocampal glutamatergic findings themselves might be important, leading to a final common blockade or inhibition of hippocampal efferent pathway activity in schizophrenia.

COGNITION

Schizophrenic persons as a group perform poorly on most neuropsychological tests when compared with normal individuals, which might be partly owing to the symptoms of schizophrenia (e.g., poor motivation or distraction from psychotic symptoms), and negative effects of early onset of the illness and chronic institutionalization leading to generalized deficits. One approach to isolate the specific neurocognitive deficits associated with schizophrenia is to look for differential deficits in persons with the illness. A generalized neurocognitive impairment will equally affect a patient's performance on all tests, as long as these tests are approximately equal with respect to difficulty. Abnormalities in the ability to abstract, problem solve, and other "executive" functions are particularly prominent in individuals with schizophrenia. Specific neuropsychological deficits include loss of memory, executive function, and motor performance, and these performance deficits are highly intercorrelated within persons. In schizophrenic persons, memory deficits are obvious (e.g., recurring digit span test), consistent with temporo-hippocampal dysfunction. Tests of frontal cortical function are altered (e.g., verbal fluency, spatial performance, pattern recognition), and long-term memory deficits have been documented. Studying identical twins discordant for schizophrenia revealed that almost all schizophrenic twins performed more poorly than their unaffected identical cotwin on all performance measures. The schizophrenic twin performed significantly worse on assessments of intelligence, memory, attention, verbal fluency, and pattern recognition than their identical twin control. The non-ill twins failed to differ in performance from unrelated normal control persons except for impairments in "logical memory" (Wechsler Scale) and in Trails A performance; in these cognitive areas performance was considerably different between the ill and non-ill twins.

Persons with schizophrenia consistently perform poorly on tasks that require sustained attention or vigilance. In addition, deficits in memory exist, including explicit memory and verbal memory. Working memory functions to keep task-relevant information "online" for brief time periods, and has received considerable focus in the schizophrenia literature. Individuals with schizophrenia show considerable failure of working memory functions. Moreover, deficits in working memory are consistent with serious disorganization and functional deterioration observed in schizophrenia spectrum, because the ability to hold information "on-line" is critical for organizing future thoughts and actions in the context of the recent past.

Whether the cognitive deficits observed in schizophrenia are primary to the illness or secondary to the symptoms can also be addressed by studying nonpsychotic relatives of schizophrenic patients with the same cognitive impairments. First degree relatives of schizophrenic probands demonstrate many of the cognitive deficits observed in schizophrenia, even though these individuals do not experience overt psychosis. These deficits include impairments in different dimensions of attention, language comprehension, verbal fluency, verbal memory, and spatial working memory. This pattern of findings has been documented by two of the most comprehensive studies of relatives of persons with schizophrenia; even after adjusting for IQ, measures of auditory attention, abstraction and verbal memory differentiated schizophrenia relatives from the unaffected comparison persons. It is unclear whether the observed neurocognitive impairments in schizophrenia relatives are fully independent or always associated with schizophrenia spectrum personality symptoms. Some studies show that schizophrenia relatives with signs of definite or probable schizotypal personality disorder have the most pronounced cognitive impairment, although not all cognitively impaired relatives met the diagnostic criteria for probable or definite schizotypal personality disorder. Other investigators using various instruments (Wisconsin card sorting test, Trail making, verbal fluency, Symbol Digit, and/or WAIS variables) have noted abnormalities among relatives of a schizophrenic probands, independent of schizotypal diagnosis.

The widespread disturbances in attention and language processing might be caused by "a disturbance in the internal representation of contextual information," potentially based on frontal cortical dysfunction and mediated by dopamine deficiency. Cognitive psychologists have suggested that a defect in the connectivity between "cognitive modules" might characterize cognition in the illness, rather than an abnormality within a single module itself. However, the concrete nature of this connectivity defect has been elusive. To complicate these considerations further, the cognitive defects are not present in every person at all times and the pattern of defects can change over time within an individual, making it difficult to propose permanent changes in connectivity in the illness and forcing a concept of dynamic or reversible functional changes.

NEUROPHYSIOLOGICAL ALTERATIONS

Abnormalities in smooth pursuit and saccadic eye movements are documented in schizophrenia. Smooth pursuit movements are

slow eye movements used to track a small moving object. The smooth pursuit eye movement abnormality has been documented in schizophrenia, is stable, and cannot be explained by disease related factors or overt psychotic symptoms. Nonpsychotic family members of schizophrenic probands also show poor pursuit globally, by pursuit gain, or by other measures. Often family members with abnormalities in smooth pursuit eye movements also have spectrum personality symptoms, although not all studies find such an association. Those studies in individuals with schizophrenia spectrum personality, with and without a known family history of schizophrenia, have noted smooth pursuit deficits only in subjects with a positive family history of schizophrenia. Smooth pursuit eye movement abnormality has been linked to chromosome 6p21 in relatives of patients with schizophrenia. Some investigators have argued that there is a deficit in motion processing in schizophrenia, thus explaining the smooth pursuit eye movement abnormality. But, because saccadic eye movements to a moving target are normal in schizophrenia, others have argued that the underlying deficit must be subsequent to the motion processing, either during the integration of motion signal into a smooth pursuit response, or the holding of the motion signal "online" for the smooth pursuit maintenance. The latter hypothesis implicates lesion(s) in posterior parietal and/or frontal cortical ocular motor regions associated with the smooth pursuit abnormality in schizophrenia, and is supported by functional imaging studies in schizophrenia spectrum.

In addition to changes in smooth pursuit, additional, subtle abnormalities in saccadic measures exist in schizophrenic patients, including failure on performing an antisaccade task in which the subject needs to look in the opposite direction of a target jump. Patients with schizophrenia made significantly more errors (i.e., made saccades to the target rather than away from the target) than the comparison groups. Nonpsychotic relatives, like schizophrenia probands themselves, also show an inability to inhibit an inappropriate saccade toward the target. This "antisaccade" deficit is modestly correlated with the smooth pursuit abnormality in the relatives of schizophrenic patients. These saccadic changes implicate dysfunction of the frontal cortex, especially the frontal eye fields in schizophrenia.

Neurophysiological studies identify abnormalities in information processing that can be elicited in the absence of a conscious behavioral response. Signal averaging of electroencephalographic (EEG) changes that are time-locked to sensory or cognitive events have been used. Such event-related potentials have several time bound segments (e.g., P50 or P300) that facilitate the examination of distinct aspects of information processing. P300 evoked potential response is a reliable positive change in an electrical potential occurring about 300 ms after a task-relevant or unexpected stimulus. P300 shows increased latency and decreased amplitude in persons with schizophrenia. Although specific EEG measures might vary with changes in symptoms, the P300 amplitude is consistently small in schizophrenia even during relative remission of psychotic symptoms. In addition, other components of evoked potential are abnormal in schizophrenia. Mismatched negativity response, an evoked EEG response occurring earlier than P300 has smaller amplitude in schizophrenia, suggesting an abnormal electrical response to stimulus novelty.

It is unclear what, if any, role these information processing deficits play in the development of clinical symptoms within the schizophrenia phenotype. However, neurophysiological paradigms that measure sensory gating provide a theoretical framework for understanding the development of the core symptoms of schizophrenia. Measures of sensory gating are obtained by examining a process called prepulse inhibition. In this paradigm, a person's ability to inhibit a startle response to a strong sensory stimulus in the presence of a preceding weak "prepulse" stimulus is evaluated. In contrast to a normal comparison group, persons with schizophrenia show poor prepulse inhibition. Schizophrenia might be associated with a reduced ability to gate sensory information, leading to a condition of sensory overload; positive symptoms could develop because of misinterpretation of unfiltered sensory information. Negative symptoms might occur due to the withdrawal from the sensory overload.

Sensory gating is also evaluated by using positive change in the evoked potentials 50 ms (P50) after each of the two auditory stimuli presented about 500 ms apart. Normal subjects show a diminished evoked potential response to the second compared with the first stimulus. In contrast, in persons with schizophrenia, the P50 evoked potential response is of similar amplitude as the response to the preceding stimulus. The ratio of amplitude of P50 response of the second (test) stimulus to the amplitude of the first (conditioning) stimulus is generally used as a measure of gating. A segregation analysis in the families of patients with schizophrenia suggested that P50 gating deficit is the result of autosomal-dominant effect of a single gene. Subsequent linkage analysis showed evidence for linkage of the gating deficit in families of schizophrenic patients with markers of location in the chromosome 15q14 region. This region has been shown to be the locus of α-7 nicotinic cholinergic receptor subunit gene, although no molecular abnormality has been found in this region of linkage.

FUNCTIONAL BRAIN ACTIVITY: rCMRglu AND rCBF

Initial studies with the early low-resolution PET cameras reported several different cortical and subcortical findings in schizophrenia. Studies reported relative hypometabolism in frontal cortex, a finding consistent with earlier SPECT blood flow studies. Early Xenon-133 rCBF studies identified and then extended the observation of frontal cortex blood flow abnormalities especially associated with impaired task performance. Schizophrenic subjects failed to activate frontal cortex areas when performing a task known to involve frontal cortex activity (e.g., Wisconsin card sort). Subsequent PET/fluorodeoxyglucose (FDG) studies in schizophrenia inconsistently detected frontal cortex hypometabolism, with some studies continuing to find it, others reporting no change in the measure, and still others finding frontal hypermetabolism. These inconsistencies can be partially explained by two plausible confounding conditions: an antipsychotic drug effect and a skewed schizophrenia target population. Antipsychotic drugs reduce cerebral metabolism in (among several sites) frontal cortex, thus possibly producing confound in the early studies that compared drug-treated schizophrenic persons with normal (untreated) controls. Also, because frontal cortical hypometabolism is associated with deficit (negative) type schizophrenia, a population skew might alter results. The composition of a patient group with drug-treated, deficit-type schizophrenics (often available for study) could skew results to identify frontal hypometabolism. Other results at first associated with the disease (e.g., elevated caudate/putamen metabolism), are now known to be a neuroleptic effect.

Studies using PET/FDG were conducted in drug-free, young, floridly psychotic schizophrenic individuals. The initial study detected metabolic differences in schizophrenia in limbic structures (anterior cingulate and hippocampal cortices) showing reduced regional metabolism in both structures. No other differences were apparent between the schizophrenic individuals and normal volunteers. However, within the schizophrenic group in this study, primary negative symptom patients showed additional changes of reduced metabolism in frontal and parietal cortex compared with the nonnegative symptom group. Both of these findings (limbic changes overall in schizophrenia, and frontal/parietal cortex reductions in negative symptoms) are consistent with other literature in their regional localization.

Blood flow studies in normal and schizophrenic persons performing hierarchical tasks within a single task modality and using contemporary scanning and analytic techniques, have begun to suggest human cerebral activation strategies associated with task performance. Because schizophrenia individuals characteristically perform many tasks more poorly than normal individuals, imaging experiments conducted without some attention to matching performance usually include a performance confound. The use of a variable error-rate task with all subjects fixed to the same performance level has been an innovation in this area, allowing comparisons across groups without a prominent performance confound. An rCBF comparison between schizophrenic patients and matched normal controls has been generated while both groups are performing a practiced auditory recognition task at a similar performance level (e.g., with task difficulty set to an 80% error level). The task involves discriminating between two auditory tones; the decibel difference in tone frequency can be varied to fix performance at 80% accuracy. There are also sensorimotor control (SMC) and rest conditions. Image analysis used in the Statistical Parametric Mapping software localized areas of activation associated with sensorimotor performance and decision during the control condition (SMC minus rest) and during the decision (decision minus SMC) condition, respectively. In the auditory recognition decision task, normal individuals activated the anterior cingulate, right insula, and right middle frontal cortex. The schizophrenic subjects had considerably more activation in extent and magnitude of response in the SMC task, showing activation not only in the superior temporal auditory cortex (left > right) but also in the left premotor cortex, left parietal cortex, right insula, and the cingulate cortex. In the decision task, especially in the ACC, schizophrenic participants showed no significant increase in activation except for a mild flow increase in right frontal cortex. Overall, in comparing the "decision minus rest" subtraction between groups, the schizophrenic patients show activation of more or less the same areas as normals. However, significantly more of this activation (which accompanied only the decision task in normals) was recruited for the relatively easy SMC task in the schizophrenic subjects. Moreover when the difficulty of the task increased and volunteers needed to increase performance, patients failed to provide additional blood flow to the ACC as did normals. Because the patients were performing this task at a similar accuracy level as controls, they must have been using other, presumably less efficient (possibly less consistent) brain regions for the task. One explanation of these data is that schizophrenic persons need "full effort" to perform the easiest of tasks. Another explanation could be that the schizophrenia volunteers all used different brain regions without consistency. One could expect a good deal of mental inefficiency with this abnormality, no matter what its explanation. These data are concretely consistent with the psychological and symptomatic abnormalities of the illness.

Other laboratories have applied this method to the localization and type of functional defects in schizophrenia. The correlation between well-delineated symptom clusters in schizophrenia (negative symptoms, hallucinations/delusions, and disorganization) and rCBF has been studied. In vivo functional manifestations associated with schizophrenia are diverse. Negative symptoms were negatively associated with rCBF in left frontal cortex and left parietal areas. Hallucinations/delusions were positively associated with flow in the left parahippocampal gyrus and the left ventral striatum. Disorganization was associated with flow in anterior cingulate and mediodorsal thalamus. This analysis shows that different brain areas are likely to be differently involved in symptom manifestations in schizophrenia, perhaps either as a cause or effect of the disorder. A subsequent PET/$H_2{}^{15}O$ study of hallucinating schizophrenic persons noted several CNS regions associated with the presence of hallucinations: the left and right thalamus, right putamen, left and right parahippocampal area, and right anterior cingulate. Cortical activations were present, but their localizations were variable between the subjects and not significant in group analysis. Another study showed that apomorphine (an antipsychotic in schizophrenia, despite being a dopamine agonist) improves (i.e., "normalizes") the anterior cingulate blood flow of schizophrenic persons during verbal fluency task performance.

Additional studies have localized changes to limbic cortex as well in schizophrenia both at rest and with cognitive challenge. Reduced hippocampal activation has been reported in schizophrenic subjects during a memory retrieval task of previously learned words. These findings (earlier) complement postmortem and structural imaging studies of abnormalities in medial temporal lobe structures of schizophrenics. A complex motor task was studied in schizophrenia during an acute illness exacerbation and 4–6 wk later after symptoms had improved. While the subjects were acutely ill, they showed signs of prefrontal hypometabolism. When the schizophrenic volunteers' symptoms improved, the prefrontal regions were normal. However, when the schizophrenic volunteers were less symptomatic, rCBF in the anterior cingulate and bilateral parietal regions was still decreased. These limbic regions' abnormalities might be the result of a dysfunctional network of regions and not a series of separate lesions.

Abnormal functional connectivity between brain regions might also explain abnormal rCBF patterns in schizophrenia. In studies of verbal fluency and semantic processing a network analysis revealed a functional disconnection between the anterior cingulate and prefrontal regions of schizophrenic subjects. Frontal lobe functional connectivity was abnormal in the schizophrenic subjects even though they had significantly activated the regions and their behavior on the tasks was not impaired. The normal circuits putatively mediating an auditory task specifically failed in connectivity between hippocampus and ACC and in influencing the prefrontal cortex. These findings are consistent with the view that the abnormalities seen in the frontal lobes of schizophrenics might be a circuitry problem of integration across regions and not a specific regional abnormality.

Several fMRI studies have explored whether rCBF changes produced by simple motor tasks are normal in schizophrenic volunteers. No rCBF differences were found between first episode, never medicated schizophrenic volunteers and normal volunteers

while were performing a sequential finger–thumb apposition task. In the same study, a decrease in the blood oxygen level dependent response in the sensorimotor cortices of schizophrenic volunteers treated with traditional (first generation) antipsychotic drugs was found. Other studies found no differences, increased rCBF in the sensorimotor cortices of the schizophrenics, or decreases in those regions. Because the schizophrenic volunteers were medicated with both traditional and atypical neuroleptics, these results suggest that previous exposure to antipsychotics can have an interactive effect with task performance and brain activation patterns.

In more cognitively demanding tasks, such as working memory tasks, fMRI results remain inconsistent. The Sternberg Item Recognition working memory paradigm was used, requiring subjects to remember either two or five digits. Unlike many PET studies of working memory, an increase was found instead of a decrease in prefrontal rCBF in the schizophrenic volunteers compared with normal controls. Use of the N-back task and the Word and Tone serial position task revealed decreases of rCBF in inferior frontal regions of the schizophrenia group. The task performance of the schizophrenia volunteers was significantly worse on the N-back and word serial position task, but was matched on the tone task. Although rCBF increases in prefrontal regions with greater working memory demands, if working memory capacity is exceeded, the activation decreases. The discrepant findings in schizophrenia might be explained by an overload of working memory in the schizophrenia group.

CLINICAL PHARMACOLOGY

Clinical therapeutics of psychotic illness began in the second half of the 20th century with the discovery of chlorpromazine's (CPZ) antipsychotic properties. All treatment advances have been based on empiric observation, not theoretical prediction. CPZ was first tested in people with schizophrenia because of its known sedative properties as a preanesthetic agent. Its selective antipsychotic activity was noticed by informed clinical observation and was subsequently demonstrated empirically. This observation became the springboard for hypotheses of altered dopaminergic transmission in schizophrenia, once the mechanism of CPZ action was identified as dopamine receptor blockade. It has generated decades of research in therapeutics, but also was pivotal in promoting pharmacological approaches to the exploration of schizophrenia pathophysiology and to its biological formulations. Drug development in schizophrenia has focused almost entirely on dopamine receptor blockade, and has been highly productive, though empiric. Many potent, clinically effective selective dopamine receptor antagonists were developed and marketed after CPZ's discovery, and are available for clinical use. The drugs are similar in their primary actions but distinctive in side effect profile. Not until the controlled study of clozapine in the late 1980s in the United States was it clearly demonstrated that this neuroleptic had a unique superior antipsychotic action in the illness. This demonstration implied that potential therapeutic gains can be expected from new pharmacological approaches. Clozapine has a unique and superior antipsychotic action in neuroleptic nonresponding schizophrenic individuals and in partially responding schizophrenics compared with CPZ. Also, clozapine produces only a very low level of motor side effects (despite its other serious side effects), thus increasing patient comfort, social adjustment, and medication compliance. Based on these clarified clinical actions of clozapine, several new clozapine-like compounds with fewer side effects, called "atypical" or second generation antipsychotics, have been developed and are available. All have reduced motor side effects, but with the exception of clozapine, do not show an advantage in treating psychosis better than first generation drugs. The pharmacological characteristics important in determining the clinical actions of the second generation antipsychotic drugs include (1) a restricted action on dopamine neurons as reflected in a limited expression of depolarization inactivation in A10 but not A9 dopamine cell body areas, (2) multiple monoamine (especially serotonin) receptor blockade, and (3) a lower dopamine receptor affinity. These second generation drugs, including risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole, have a primary antipsychotic action at least equivalent to first generation drugs, but have considerably lower motor side effects (parkinsonism, and akathesia) and possibly improved effects on cognition. Where available, use has switched completely from first to second generation drugs with considerable increases in patient satisfaction. Other improvements in medication compliance and clear improvements in psychosocial function remain to be demonstrated. Only dopamine receptor antagonists and a partial dopamine agonist of the dopamine$_2$-family show broad and potent antipsychotic efficacy in schizophrenia.

To understand the cerebral mechanisms of antipsychotic drug action, PET with FDG was used to study the localization of haloperidol action in the schizophrenic brain. Reports of the increase in glucose metabolism in the caudate and putamen with typical neuroleptics, were confirmed. It also found an increase in metabolism in the anterior thalamus and a decrease in metabolism in the frontal cortex (middle and inferior gyri) and anterior cingulate areas. Based on the known anatomic connections between basal ganglia structures and neocortex, these data can be interpreted as showing a primary drug action of haloperidol in the basal ganglia (caudate and putamen) with secondary and tertiary effects being propagated to these other related brain areas over the cortical-subcortical parallel-distributed neuronal circuits. This interpretation of haloperidol action is consistent with the idea that the drug acts primarily in the caudate-putamen with that action distributed to other related brain areas through the well-described parallel segmented cortical–subcortical motor circuit. This theory of anti-dopaminergic antipsychotic drug mechanisms needs expansion and further testing. Other mechanisms also known to diminish dopamine-mediated neurotransmission have been shown to be antipsychotic, although they do not seem as potent or as consistently effective as the dopamine$_2$-family receptor antagonists. An effect was initially demonstrated with tetrabenazine, a dopamine synthesis inhibitor; co-treatment with this drug decreased the dose of thioridazine required for full schizophrenia treatment, tested in a case-controlled study. Also reserpine, which depletes dopamine stores from nerve terminals, shows antipsychotic activity in schizophrenia and other psychoses. This action of reserpine, known before the discovery of neuroleptics, was used to treat acute psychosis, but with considerable side effect burden. The evaluation of full and partial dopamine agonists has been tested theoretically in schizophrenia. Dopamine agonists reduce dopamine synthesis and release by their action at the dopamine autoreceptor. The antipsychotic actions of drugs like apomorphine and (-)-3-hydroxyphenyl-N-propyl piperidine in schizophrenia might be based on an autoreceptor mechanism, namely a stimulation of dopamine autoreceptors to diminish dopamine release and thereby diminish dopamine mediated neurotransmission. These strategies for therapeutics have now been translated into clinical

practice with the development of aripiprazole, a partial dopamine agonist.

There is no clear evidence from multicenter trials that glutamatergic drugs are therapeutic in schizophrenia, but there are reasons to be interested in this system's pharmacology in the illness. First, the excitatory amino acid (EAA) system with glutamate is ubiquitous in the brain; nearly every CNS cell bears EAA-sensitive receptors, indicating the extent of this system's influence. It is a complex system with at least two major transmitters (glutamate and aspartate) and probably several minor ones; it has at least four families of receptors, three ionotropic (NMDA-sensitive, AMPA, and kainate) and several metabotropic families with each receptor having a unique distribution, pharmacology, and probably distinctive functions. EAAs are the chief excitatory neurotransmitters in brain. They mediate fast information transmission functions and are also thought to be involved in other kinds of brain activity, such as developmental pruning, learning and memory, and neuronal plasticity. A therapeutic action of d-cycloserine (an NMDA-sensitive glutamatergic coagonist at the glycine receptor) and high doses of glycine (precursor) as a cotreatment for negative schizophrenic symptoms with first generation antipsychotics has been reported. Certainly the EAAs must mediate some aspects of psychosis due to their ubiquitous involvement in the CNS. Whether they might be involved in schizophrenia in a more primary way is speculation.

A connection between a part of the glutamate system, the NMDA-sensitive glutamate receptor system, and schizophrenia can be suspected because of the actions of PCP and its congener ketamine on human cognition. PCP produces a complex array of behaviors in humans including a psychotomimetic state. It can induce a psychotic state in normal persons (without delirium) characterized by many signs and symptoms often found in schizophrenia. Moreover, PCP and ketamine can both selectively exacerbate a patient's psychotic symptoms in schizophrenia, suggesting an action on (or near) the site of schizophrenia pathophysiology. Associated with the NMDA-sensitive glutamate receptor is a PCP recognition site located inside the NMDA-gated ion channel; the PCP site antagonizes ionic flow through the channel. This is a complex receptor site where NMDA, glycine, and polyamines positively gate ion flow into the cell and PCP, Zn^{2+}, and Mg^{2+} inhibit flow. It is presumed that PCP and ketamine both exert several important behavior actions through effects at this NMDA receptor.

Ketamine causes psychosis-like experiences in normal persons, exacerbates psychosis in schizophrenia, and functionally affects rCBF directly in those brain areas already identified as abnormal in schizophrenia, the ACC and hippocampus. Behaviorally, ketamine increases psychosis at subanesthetic doses in both neuroleptic-treated and neuroleptic-free schizophrenic patients to approximately the same degree. Ketamine stimulates positive symptoms in schizophrenia, and its action is not blocked by dopamine receptor antagonism. Ketamine stimulates a person's characteristic set of schizophrenic hallucinations, delusions, and/or thought disorder without totally inducing a new psychotomimetic state. This is unlike other psychotomimetics (e.g., amphetamine or muscimol), which stimulate psychotomimetic symptoms typical of the drug, not the illness. This ketamine action would be most parsimoniously explained by assuming that the drug stimulates a brain system that is already active in mediating the psychosis.

CONCLUSION

Schizophrenia is a serious mental illness. Persons with this illness are severely disadvantaged in life to the extent they cannot hold a job or maintain a family structure because of the breadth of mental symptoms influencing thought structure, thought content, affect, and cognition. Drug treatments reduce symptoms and blunt manifestations, but do not eliminate disease features. New therapeutics research needs to build on a known pathophysiology with well-supported molecular targets for drug discovery.

129 Disorders of Substance Abuse and Dependence

Eric J. Nestler and Jennifer Chao

SUMMARY

Drug addiction continues to exact enormous human and financial costs on society, at a time when available treatments remain inadequately effective for most people. Given that advances in treating other medical disorders have resulted directly from research of the molecular and cellular pathophysiology of the disease process, an improved understanding of the basic neurobiology of addiction should likewise translate into more efficacious treatments. This chapter reviews our knowledge of circuits in the brain that mediate addiction and the changes in these circuits, induced by drugs of abuse at the molecular level, which represent the pathophysiology of addiction.

Key Words: Brain reward regions; cAMP; cocaine; CREB (cAMP response element binding protein); dopamine; drug addiction; drugs of abuse; ΔFosB; gene expression; nucleus accumbens; opiates; transcription factors; ventral tegmental area.

INTRODUCTION

According to the *Diagnostic and Statistical Manual of Mental Disorders*, drug addiction is referred to as "*substance dependence*," the essential characteristic of which is a compulsive pattern of drug-seeking and drug-taking behavior that continues despite adverse consequences of drug use. Addiction, however, is by far the preferable term, because dependence—a pharmacological term—describes just one of many types of adaptations to drug exposure that includes addiction. *Dependence* refers to drug-induced adaptations that compensate for drug exposure and lead to an array of *withdrawal* symptoms when drug use ceases. Withdrawal symptoms vary based on the substance, but usually involve a significant negative affective state (dysphoria), and in some cases profound somatic abnormalities. *Tolerance* refers to drug-induced adaptations that lead to diminishing effects of a constant drug dose. *Sensitization*, or reverse tolerance, is caused by drug-induced adaptations that enhance drug responsiveness with repeated drug exposure. Many drugs cause both tolerance and sensitization, with some drug effects decreasing over time whereas others increase.

The complex syndrome of addiction is believed to be caused by a compilation of these types of pharmacological adaptations to repeated drug exposure that occur in many brain regions important for the regulation of reward, motivation, and affective state. This chapter reviews the advances that have been made over the past several decades to understand the initial mechanisms by which drugs of abuse influence reward centers in the brain, and provides a progress report of efforts to identify the precise adaptations to repeated drug exposure that are responsible for addiction.

ACUTE MECHANISMS OF DRUG ACTION

The acute protein targets for most drugs of abuse are known as is considerable detail about how those actions perturb synaptic transmission after initial exposure to the drugs (Table 129-1). For example, opiates are agonists at opioid receptors, and cocaine binds to and inhibits the nerve terminal transporters for dopamine or other monoamine neurotransmitters. Thus, drugs of abuse comprise chemically divergent molecules with different initial activities. Yet, each of these drugs can produce addiction, which shares key features. Each drug, despite many distinct actions in the brain, converges in producing some common actions.

Prominent among these common actions is activation of the mesolimbic dopamine system (Fig. 129-1), which involves increased dopaminergic transmission from the ventral tegmental area (VTA) of the midbrain to the nucleus accumbens (NAc) (also called ventral striatum) and other regions of the limbic forebrain (e.g., prefrontal cortex). Several drugs of abuse also converge by mimicking (opiates) or activating (alcohol, nicotine) endogenous opioid pathways that innervate the VTA and NAc. Other drugs appear to act directly in the NAc via other mechanisms (e.g., cannabinoids, phencyclidine). These several actions appear to produce some similar net effects (generally inhibition) on medium spiny neurons of the NAc, in part because opioid, cannabinoid, and certain dopamine receptors, all of which are Gi-coupled (*see* Table 129-1), are expressed by some of the same NAc neurons. There is compelling evidence that these various mechanisms play a central role in mediating the acute rewarding properties shared by all drugs of abuse. The mesolimbic dopamine system and its forebrain targets are very old from an evolutionary point of view and are part of the brain's motivational system that regulates responses to natural rewards such as food, drink, sex, and social interaction. It is thought that drugs of abuse affect this pathway with a power and persistence probably not seen in response to natural rewards and, consequently, induce chronic adaptations that underlie addiction.

Table 129-1
Acute Actions of Some Drugs of Abuse

Drug	*Action*	*Receptor signaling mechanism*
Opiates	Agonist at μ, δ, and κ opioid receptors[a]	Gi
Cocaine	Indirect agonist at dopamine receptors by inhibiting dopamine transporters[b]	Gi and Gs[c]
Amphetamine	Indirect agonist at dopamine receptors by stimulating dopamine release[b]	Gi and Gs[c]
Ethanol	Facilitates $GABA_A$ receptor function and inhibits NMDA glutamate receptor function[d]	Ligand-gated channels
Nicotine	Agonist at nicotinic acetylcholine receptors	Ligand-gated channels
Cannabinoids	Agonist at CB_1 and CB_2 cannabinoid receptors[e]	Gi
Phencyclidine	Antagonist at NMDA glutamate receptors	Ligand-gated channels
Hallucinogens	Partial agonist at $5HT_{2A}$ serotonin receptors	Gq
Inhalants	Unknown	

[a]Activity at μ (and possibly) δ receptors mediates the reinforcing actions of opiates; κ receptors mediate aversive actions.

[b]Cocaine and amphetamine exert analogous actions on serotonergic and noradrenergic systems, which may also contribute to the reinforcing effects of these drugs.

[c]Gi couples D_2-like dopamine receptors, and Gs couples D_1-like dopamine receptors, both of which are important for dopamine's reinforcing effects.

[d]Ethanol affects several other ligand-gated channels, and at higher concentrations voltage-gated channels, as well. In addition, ethanol is reported to influence many other neurotransmitter systems, including serotonergic, opioidergic, and dopaminergic systems. It is not known whether these effects are direct or achieved indirectly via actions on various ligand-gated channels.

[e]Activity at CB_1 receptors mediates the reinforcing actions of cannabinoids; CB_2 receptors are expressed in the periphery only. Proposed endogenous ligands for the CB_1 receptor include the arachidonic acid metabolites, anandamide, and 2-arachidonylglycerol.

GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

Although the field has focused primarily on the VTA–NAc pathway as a key mediator of acute drug reward and addiction, several other brain regions are also important, and recent work has begun to examine these regions for chronic adaptations to repeated drug exposure (*see* Fig. 129-1). The amygdala is particularly important for conditioned aspects of drug exposure, for example, establishing associations between environmental cues and both the rewarding actions of acute drug exposure and the aversive symptoms of drug withdrawal. The hippocampus, a traditional memory circuit, is no doubt critical for memories of the context of drug exposure and withdrawal. The hypothalamus is important for mediating vast effects of drugs on the body's physiological state. Probably the most important, but least understood, are frontal regions of cerebral cortex, such as medial prefrontal cortex, anterior cingulate cortex, and orbitofrontal cortex, which provide executive control over drug use, which is severely impaired in many addicts. Of course, these various brain regions, and many more, do not function separately. Rather, they are parts of a complex and highly integrated circuit that is profoundly altered by drug exposure.

CHRONIC ADAPTATIONS TO DRUG EXPOSURE

Drugs of abuse change literally hundreds of proteins in the various reward-related brain regions previously mentioned. Rather than providing a comprehensive review of such drug-induced changes, this chapter focuses on well-characterized changes that contribute to particular features of the behavioral syndrome of addiction.

UPREGULATION OF THE cAMP PATHWAY One of the best-established adaptations to chronic drug exposure is upregulation of the cAMP pathway after chronic opiate administration, illustrated in Fig. 129-2. Acutely, opiates inhibit the functional activity of the cAMP pathway by inhibiting adenylyl cyclase, the enzyme that catalyzes the synthesis of cAMP. With continued opiate exposure, inhibition of the cAMP pathway gradually recovers, which can be viewed as a sign of tolerance. This recovery can also be viewed as a sign of dependence, because on removal of the opiate (e.g., by administration of an opioid receptor antagonist such as naloxone) activity of the cAMP pathway increases far above control levels (which can be viewed as a sign of withdrawal).

Upregulation of the cAMP pathway in response to chronic opiate administration was demonstrated in cultured neuroblastoma × glioma cells in culture, and later shown to occur in several brain regions in vivo. The molecular mechanisms by which this upregulation occurs are now partly understood (*see* Fig. 129-2). With chronic opiate administration there is a gradual induction of adenylyl cyclase and of cAMP-dependent protein kinase (protein kinase A), which mediates most of the effects of cAMP on neuronal function. Some of these effects occur at the level of gene expression (*see* Adaptations In Gene Expression). Induction of these enzymes opposes acute opiate inhibition of adenylyl cyclase and explains the recovery in the functional activity of the cAMP pathway with repeated opiate administration (tolerance and dependence). On removal of the opiate, the upregulated cAMP pathway is no longer inhibited and becomes fully activated functionally (withdrawal).

Opiate-induced upregulation of the cAMP pathway occurs in many regions of the brain, in which it is implicated in several features of addiction, depending on the role of that brain region (Table 129-2). Moreover, in at least one region, the NAc, several drugs of abuse in addition to opiates (e.g., cocaine and alcohol) cause a similar upregulation of the cAMP pathway. Thus, this molecular adaptation can be viewed as a common adaptation to drug exposure and perhaps a common mechanism of addiction. One of the consequences of cAMP pathway upregulation is the sustained activation of the transcription factor cAMP response element-binding protein (CREB). Evidence for a role of the cAMP pathway and CREB in the NAc in particular aspects of addiction is discussed later.

ADAPTATIONS IN RECEPTOR SENSITIVITY Several pharmacological adaptations thought to contribute to addiction (e.g., tolerance and sensitization) involve changes in the sensitivity of neurotransmitter receptor function. Hence, effort has been directed toward understanding the molecular basis of such changes.

The best-characterized mechanism concerns trafficking of the opioid receptor. When an opiate binds to an opioid receptor, it initiates a negative feedback pathway. The opiate-bound receptor becomes a good substrate for G protein receptor kinases (GRKs), a class of protein kinase that phosphorylates ligand-bound G protein-coupled receptors. This triggers the binding of the receptor to another protein, called arrestin, which then triggers internalization

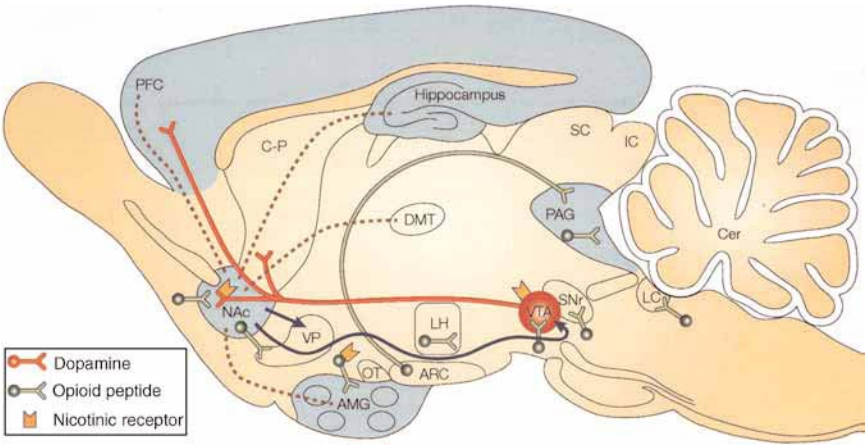

Figure 129-1 Key neural circuits of addiction. *Dotted lines* indicate limbic afferents to the NAc. *Arrows* represent efferents from the NAc thought to be involved in drug reward. *Dopamine pathways* indicate projections of the mesolimbic dopamine system thought to be a critical substrate for drug reward. This system originates in the VTA and projects to the NAc and other limbic structures, including olfactory tubercle (OT), ventral domains of the caudate-putamen (C-P), amygdala (AMG), and prefrontal cortex (PFC). *Opioid peptide pathways* indicate opioid peptide-containing neurons, which are involved in opiate, ethanol, and possibly nicotine reward. These opioid peptide systems include the local enkephalinergic circuits (short segments) and the hypothalamic midbrain beta-endorphin circuit (long segment). *Shaded areas* indicate the hypothesized distribution of $GABA_A$ receptor complexes, which may contribute to ethanol reward. *Nicotinic receptors* indicate nicotinic acetylcholine receptors hypothesized to be located on dopaminergic and opioid peptidergic systems. ARC, arcuate nucleus; Cer, cerebellum; DMT, dorsomedial thalamus; GABA, γ-aminobutyric acid; PFC prefrontal cortex; IC, inferior colliculus; LC, locus ceruleus; LH, lateral hypothalamus; PAG, periaqueductal gray; SC, superior colliculus; SNr, substantia nigra pars reticulata; VP, ventral pallidum. (Please *see* color insert.)

of the receptor and receptor desensitization, contributing to receptor tolerance. Such receptor internalization is dependent on G protein βγ-subunits and appears to be a dynamin-mediated process. Indeed, mice lacking certain arrestins or GRKs show reduced opiate tolerance. Interestingly, dopamine receptors are regulated by analogous mechanisms. Accordingly, mice lacking arrestins or GRKs also showed abnormal behavioral adaptations to cocaine and other stimulants.

Drug-induced adaptations in G proteins or proteins that regulate G proteins—for example, regulators of G protein signaling (RGS) proteins—represent additional mechanisms of altered receptor sensitivity. Drug-induced changes in particular G protein subunits occur in specific brain regions and in some cases relate to drug tolerance or sensitization. RGS proteins serve as GTPase activating proteins; they activate the GTPase activity intrinsic to G protein α-subunits, which normally terminates the G protein signal. Over 25 forms of RGS proteins are known and most show highly restricted patterns of expression in brain. Chronic exposure to opiates, cocaine, or other drugs of abuse alters levels of particular RGS subtypes in brain regions important for addiction, such as the NAc. Moreover, such changes have been directly implicated in mechanisms of drug tolerance or sensitization depending on the brain region involved.

ADAPTATIONS IN NEUROTRANSMITTER SYSTEMS

Implicit in this discussion is the idea that chronic drug exposure alters the activity of particular neurotransmitter systems in the brain and that such alterations contribute to addiction. Changes in receptor sensitivity, presented in the previous section, are just one possible mechanism of adaptations in neurotransmitter systems. Although numerous neurotransmitter systems undergo such drug-induced adaptations, this chapter focuses on three neurotransmitters.

Dopamine A widely held view is that repeated exposure to a drug of abuse produces some of its behavioral effects, for example, drug craving and locomotor sensitization, by facilitating drug-induced dopamine release in the NAc. However, literature on this subject is inconsistent and confusing, given that these drugs both increase and decrease synaptic levels of dopamine depending on the drug treatment regimen employed and the time of withdrawal studied. Further work, therefore, is needed to understand precisely how altered regulation of dopamine release in the NAc or other brain regions contributes to the behavioral abnormalities of addiction. Further investigation is also needed to identify the molecular targets of drugs of abuse that mediate the altered synaptic levels of dopamine observed. Possibilities include drug regulation of the dopamine transporter and dopamine synthetic enzymes, such as tyrosine hydroxylase.

Glutamate Drug-induced adaptations in glutamate systems have gained significant attention because of their prominent interactions with VTA and NAc function: projections from amygdala, frontal cortical regions, and hippocampus, which regulate the mesolimbic dopamine system, are largely glutamatergic. Accordingly, glutamate receptor antagonists can block the development of locomotor sensitization to stimulants and opiates, as well as some electrophysiological perturbations in mesolimbic dopamine function that accompany repeated stimulant exposure. Moreover, repeated stimulant exposure increases and decreases, respectively, the electrophysiological responsiveness of VTA dopamine neurons and NAc neurons to glutamate. Supersensitivity of VTA dopamine neurons to glutamate could be mediated via upregulation of specific glutamate receptor subunits in this region, specifically glutamate receptor 1**,** which has been seen after chronic cocaine, opiates, or ethanol administration. Altered levels of glutamate receptor subunits in the NAc are more variable, with both decreases in early withdrawal and increases in late withdrawal reported.

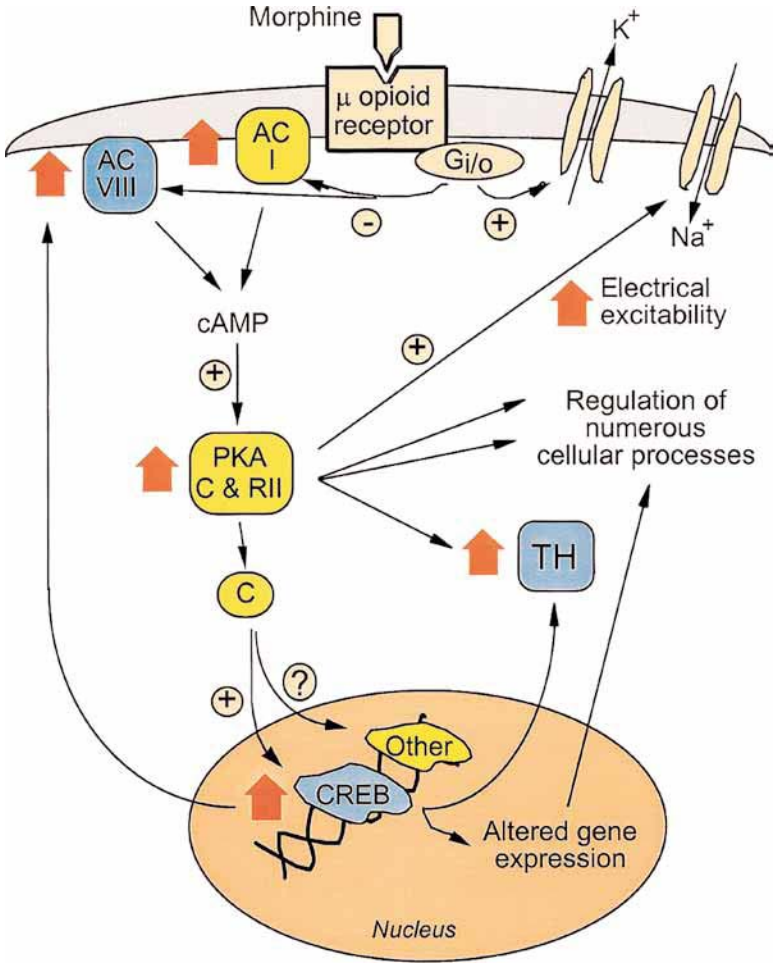

Figure 129-2 Scheme illustrating upregulation of the cAMP pathway in the locus ceruleus (LC), one target for opiates in the brain. Opiates acutely inhibit LC neurons by increasing the conductance of an inwardly rectifying K^+ channel via coupling with subtypes of Gi/o, and by decreasing a Na^+-dependent inward current via coupling with Gi/o and the consequent inhibition of adenylyl cyclase. Reduced levels of cAMP decrease PKA activity and the phosphorylation of the responsible channel or pump. Inhibition of the cAMP pathway also decreases phosphorylation of numerous other proteins and thereby affects many additional processes in the neuron. For example, it reduces the phosphorylation state of CREB, which may initiate some of the longer-term changes in locus ceruleus function. Upward bold arrows summarize effects of chronic morphine in the locus ceruleus. Chronic morphine increases levels of types I (ACI) and VIII (ACVIII) adenylyl cyclase, PKA catalytic (C) and regulatory type II (RII) subunits, and several phosphoproteins, including CREB and tyrosine hydroxylase (TH), the rate-limiting enzyme in norepinephrine biosynthesis. These changes contribute to the altered phenotype of the drug-addicted state. For example, the intrinsic excitability of LC neurons is increased via enhanced activity of the cAMP pathway and Na^+-dependent inward current, which contributes to the tolerance, dependence, and withdrawal exhibited by these neurons. Upregulation of ACVIII and TH is mediated via CREB, whereas upregulation of ACI and of the PKA subunits appears to occur via a CREB-independent mechanism not yet identified. (Reproduced with permission from Nestler EJ, Aghajanian GK. Molecular and cellular basis of addiction. Science 1997;278:58–63.)

Interest in drug-induced adaptations in glutamatergic systems has been sparked in part by the increasing evidence that such changes in glutamate transmission resemble changes in other brain regions that have been implicated in cellular mechanisms of learning and memory. For example, long-term potentiation in the CA1 region of hippocampus involves NMDA glutamate receptor-mediated changes in sensitivity of α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) glutamate receptors. This may occur via activation of Ca^{2+}-activated protein kinases, the phosphorylation of AMPA receptors, and the subsequent activation of the receptors as well as their delivery to the plasma membrane from intracellular stores. Research has demonstrated long-term potentiation and related forms of synaptic plasticity at glutamatergic synapses in the VTA and NAc and their regulation by drugs of abuse. An attractive hypothesis is that aspects of addiction are driven by memory-like processes within the reward regions of brain. This principle is discussed later.

Corticotropin-Releasing Factor Corticotropin-releasing factor (CRF) is best known as the hypothalamic peptide that regulates adrenocorticotropin hormone from the pituitary, part of the classic stress response. However, hypothalamic neurons that express CRF also influence many brain regions, and CRF is a prominent transmitter elsewhere in brain, for example, the amygdala. In both locations, CRF would be expected to influence the effects of drugs of abuse on the brain. Indeed, drug-induced alterations in CRF systems in the hypothalamus and the amygdala have been implicated in mediating the ability of stress to induce relapse to drug use. CRF systems also contribute to the negative emotional systems of drug withdrawal, a role documented for several drugs of abuse.

Table 129-2
Upregulation of the cAMP Pathway and Opiate Addiction

Site of upregulation	*Functional consequence*
Locus ceruleus[a]	Physical dependence and withdrawal
Ventral tegmental area[b]	Dysphoria during early withdrawal periods
Periaqueductal gray[b]	Dysphoria during early withdrawal periods, and physical dependence and withdrawal
Nucleus accumbens	Dysphoria during early withdrawal periods
Amygdala	?Conditioned aspects of addiction
Dorsal horn of spinal cord	Tolerance to opiate-induced analgesia
Myenteric plexus of gut	Tolerance to opiate-induced reductions in intestinal motility and increases in motility during withdrawal

[a]The cAMP pathway is upregulated within the principal noradrenergic neurons located in this region.

[b]Indirect evidence suggests that the cAMP pathway is upregulated within GABAergic neurons that innervate the dopaminergic (ventral tegmental area) and serotonergic (periaqueductal gray) neurons located in these regions. During withdrawal, the upregulated cAMP pathway would become fully functional and could contribute to a state of dysphoria by increasing the activity of the GABAergic neurons, which would then inhibit the dopaminergic and serotonergic neurons.

GABA, γ-aminobutyric acid.

ADAPTATIONS IN GENE EXPRESSION The precise molecular mechanisms by which chronic drug exposure alters levels of specific proteins in the VTA–NAc pathway are still unknown, but gene expression may be involved. Such studies have focused on the role of two families of transcription factors: CREB family proteins, and Fos and Jun family proteins, in particular ΔFosB. CREB proteins regulate transcription by binding as dimers to specific DNA sequences termed cAMP response element sites, whereas Fos and Jun proteins form heterodimeric complexes that bind to DNA sequences named activator protein-1 sites. Most genes likely contain numerous response elements for these and many other transcription factors, suggesting that complex interactions among multiple mechanisms control the expression of a given gene.

CREB As mentioned, chronic exposure to opiates, cocaine, or alcohol upregulates the cAMP pathway in the NAc and, as expected, this is associated with sustained activation of CREB in this region. Perspective into the functional role of the upregulated cAMP pathway and CREB in addiction has come from a series of studies examining the behavioral manifestations of a localized increase in CREB activity in the NAc. First, bilateral intra-NAc infusions of a PKA activator decreased cocaine reward in rats, whereas infusion of PKA inhibitors increased cocaine reward. Studies overexpressing CREB in the rat NAc via viral-mediated gene transfer have provided more direct evidence of the effects of CREB activity on reward. Increased CREB expression decreases the rewarding effects of cocaine, opiates, and sucrose, a natural reward, whereas expression of a dominant-negative mutant form of CREB resulted in opposite effects. Similarly, inducible transgenic mice overexpressing CREB in the NAc and dorsal striatum exhibit decreased drug reward, and mice lacking CREB show the opposite responses. Together, these data indicate that upregulation of the cAMP pathway and CREB in the NAc as a result of chronic drug administration decreases the rewarding effects of drugs of abuse and can be viewed as a mechanism of tolerance.

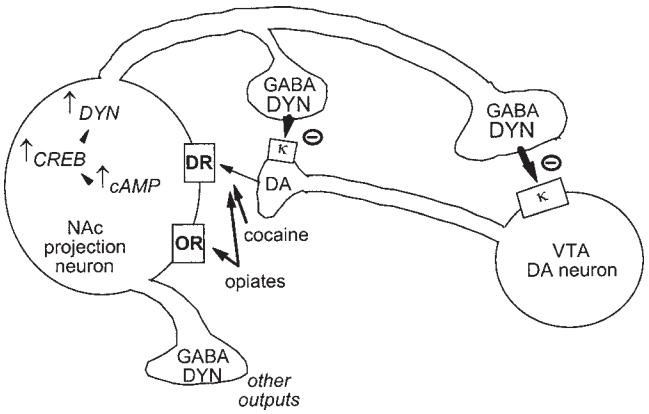

Figure 129-3 Regulation of CREB by drugs of abuse. The figure shows a VTA (ventral tegmental area of the midbrain) dopamine (DA) neuron innervating a class of NAc GABAergic projection neuron that expressed dynorphin (dyn). Dynorphin serves a negative feedback mechanism in this circuit; dynorphin, released from terminals of the NAc neurons, acts on κ opioid receptors located on nerve terminals and cell bodies of the DA neurons to inhibit their functioning. Chronic exposure to cocaine or opiates upregulates the activity of this negative feedback loop via upregulation of the cAMP pathway, activation of CREB, and induction of dynorphin. (Reproduced with permission from Nestler EJ. Molecular basis of long-term plasticity underlying addiction. Nat Rev Neurosci 2001;2:119–128. Copyright Nature Publishing Group.) CREB, cAMP response element-binding protein; DR, dopamine receptor; GABA, γ-aminobutyric acid; OR, opioid receptor.

Efforts are underway to identify target genes for CREB in the NAc. One apparent target is dynorphin, an opioid peptide expressed in a subset of medium spiny neurons in the NAc, which is induced in this region after chronic drug exposure (Fig. 129-3). Dynorphin release from the NAc is implicated in mediating dysphoria during withdrawal through a negative feedback loop to VTA dopamine neurons. Dynorphin binds to κ opioid receptors on VTA dopamine neuron cell bodies and terminals to inhibit their activity and decrease DA release in the NAc. The cocaine aversion caused by CREB overexpression in the NAc can be attenuated with a κ opioid antagonist.

ΔFosB Acute exposure to drugs of abuse rapidly (1–4 h) induces all Fos family members in the NAc and dorsal striatum (Fig. 129-4). Even with continued drug exposure, levels of these proteins decline rapidly toward basal levels within 8–12 h. Biochemically modified isoforms of ΔFosB (a truncated splice variant of the FosB gene) exhibit a different expression pattern. Acutely, ΔFosB expression is only modestly induced, but it persists long after the other Fos family members have returned to basal levels. This persistence is mediated by the high level of stability of the ΔFosB isoforms. As a result, ΔFosB levels gradually accumulate after repeated drug exposure and can persist for weeks after withdrawal, dynamics that allow it to play a longer-term role in drug regulation of gene expression. Also, ΔFosB expression is induced in response to chronic exposure to several drugs of abuse, including cocaine, amphetamine, opiates, nicotine, ethanol, and phencyclidine. Such induction is most prominent in the NAc and dorsal striatum, but is seen to a lesser extent in other brain regions known to be important in addiction, including the amygdala and prefrontal cortex. Further, ΔFosB accumulates in the NAc after excessive running behavior, suggesting that such induction may occur in response to many types of compulsive behaviors.

Based on its unique properties, the functional significance of ΔFosB in drug-related behaviors has been studied extensively.

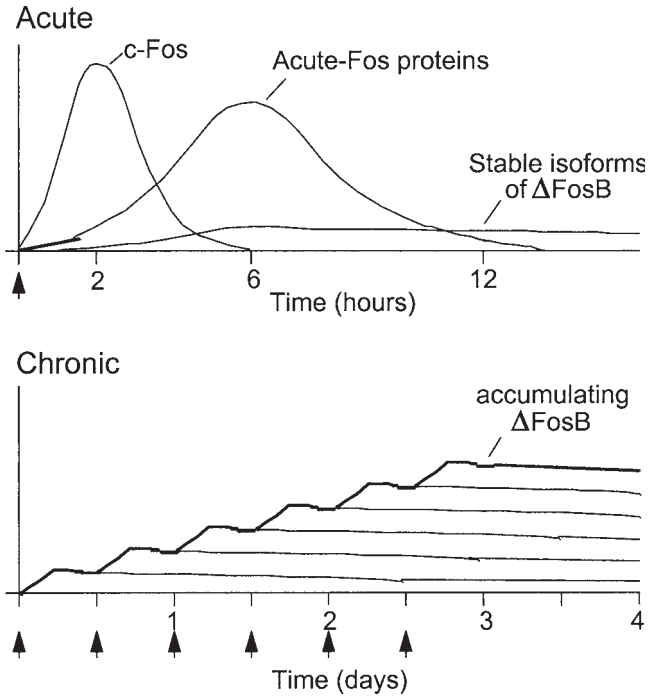

Figure 129-4 Scheme for the gradual accumulation of ΔFosB vs the rapid and transient induction of acute Fos family proteins in brain. **(A)** Several waves of Fos-like proteins are induced in neurons by acute stimuli. c-Fos is induced rapidly and degraded within several hours of the acute stimulus, whereas other "Acute Fos proteins" (i.e., FosB, ΔFosB, and Fos-related antigen [Fra]-1 and -2) are induced somewhat later and persist somewhat longer than c-Fos. Stable isoforms of ΔFosB are also induced at low levels following a single acute simulus but persist in brain for long periods. In a complex with Jun-like proteins, these waves of Fos proteins form activator protein-1 binding complexes with shifting composition over time. **(B)** With repeated (e.g., twice daily) stimulation, each acute stimulus induces low levels of stable ΔFosB isoforms. This is indicated by the lower set of overlapping lines, which indicate ΔFosB induced by each acute stimulus. The result is a gradual increase in the total levels of ΔFosB with repeated stimuli during a course of long-term treatment, indicated by the increasing stepped line in the graph. The increasing levels of ΔFosB with repeated stimulation would result in the gradual induction of significant levels of a long-lasting AP-1 complex, which is hypothesized to underlie persisting forms of neural plasticity in the brain. (Reproduced with permission from Nestler EJ. Molecular basis of long-term plasticity underlying addiction. Nat Rev Neurosci 2001;2: 119–128. Copyright Nature Publishing Group.)

Transgenic mice were generated that confer inducible expression of ΔFosB primarily in the NAc and dorsal striatum. On ΔFosB expression, the mice show increased sensitivity to the locomotor activating and rewarding properties of cocaine and morphine. The mice also self-administer cocaine at lower doses and work harder for cocaine self-administration. These findings indicate that ΔFosB may play a role in sensitizing animals to the rewarding effects of cocaine and opiates as well as in increasing relapse when the drug is withheld. In addition, ΔFosB expression increases running activity, demonstrating a similar effect on natural rewards. Finally, mice that inducibly express a dominant negative antagonist of ΔFosB in the NAc and dorsal striatum show a decrease in cocaine reward, as expected. Thus, ΔFosB accumulation could amount to a "molecular switch," whose uniquely stable expression bridges the gap between acute responses to drug exposure and long-term adaptations in the neural and behavioral plasticity of addiction.

A major goal of research is to identify ΔFosB target genes. Using the candidate gene approach, two target genes have been identified. ΔFosB mediates the ability of cocaine to upregulate the AMPA glutamate receptor subunit glutamate receptor 2 in the NAc and could thereby mediate some of the drug-induced changes in glutamatergic transmission discussed earlier. Another potential target gene of ΔFosB is dynorphin. In contrast to CREB's induction of dynorphin, ΔFosB decreases expression of the neuropeptide, which could further contribute to the enhancement of reward sensitivity seen with ΔFosB induction.

Another approach to identifying potential ΔFosB target genes has been through the use of DNA microarrays. Inducible overexpression of ΔFosB regulates the expression of several genes in the NAc and other regions. The transcriptional regulation of these genes by ΔFosB requires additional confirmation, and their significance to drug-related plasticity has yet to be elucidated. However, one putative ΔFosB target gene identified by DNA microarray analysis is cyclin-dependent kinase 5 (Cdk5), which was subsequently found to be induced in the NAc and dorsal striatum by chronic cocaine. A possible function of Cdk5 in addiction plasticity is discussed later in this chapter; however, it is significant that its identification and subsequent characterization was enabled through the use of DNA microarrays.

CONSOLIDATION OF DRUG-INDUCED ADAPTATIONS

Although induction of ΔFosB is the most long-lived molecular adaptation known to occur in response to a drug of abuse, it does undergo proteolysis at a finite rate and therefore cannot underlie the near-permanent changes in behavior that are seen in many addicted individuals. This dilemma is analogous to challenges faced in the learning and memory field: although there are many elegant molecular and cellular models of memory, no long-lived molecular adaptations have yet been identified that could account for highly stable behavioral memory. By analogy with the learning and memory field, an evolving view in the addiction field is that some form of consolidation is needed, in the context of chronic drug exposure, to cause particularly long-lived adaptations in the brain.

One possibility, which remains highly speculative, is that such consolidation is mediated by structural changes in neurons. Indeed, drugs of abuse produce morphological changes in particular neuronal cell types after long-term administration. Repeated opiate exposure decreases the size and caliber of dendrites and soma of midbrain dopamine neurons that innervate the NAc. The functional consequences of these changes are unknown, but they could reflect a downregulation of dopaminergic activity and contribute to the dysphoria of drug withdrawal states. In contrast, repeated stimulant exposure increases the number of dendritic spines and dendritic branch points both of medium spiny neurons in the NAc and of pyramidal neurons in the medial prefrontal cortex (both of which receive dopaminergic inputs) (Fig. 129-5). These latter changes persist for at least 1 mo after the last drug exposure. It has been proposed that such structural changes could represent the neural substrates for the near-permanent sensitization in drug responsiveness seen in some models of addiction.

Of course, these various observations raise the critical question of the underlying molecular and cellular mechanisms that mediate such alterations in neural structure. Studies of the VTA–NAc pathway suggest that neurotrophic factors could be involved. Infusion of brain-derived neurotrophic factor into the VTA promotes the

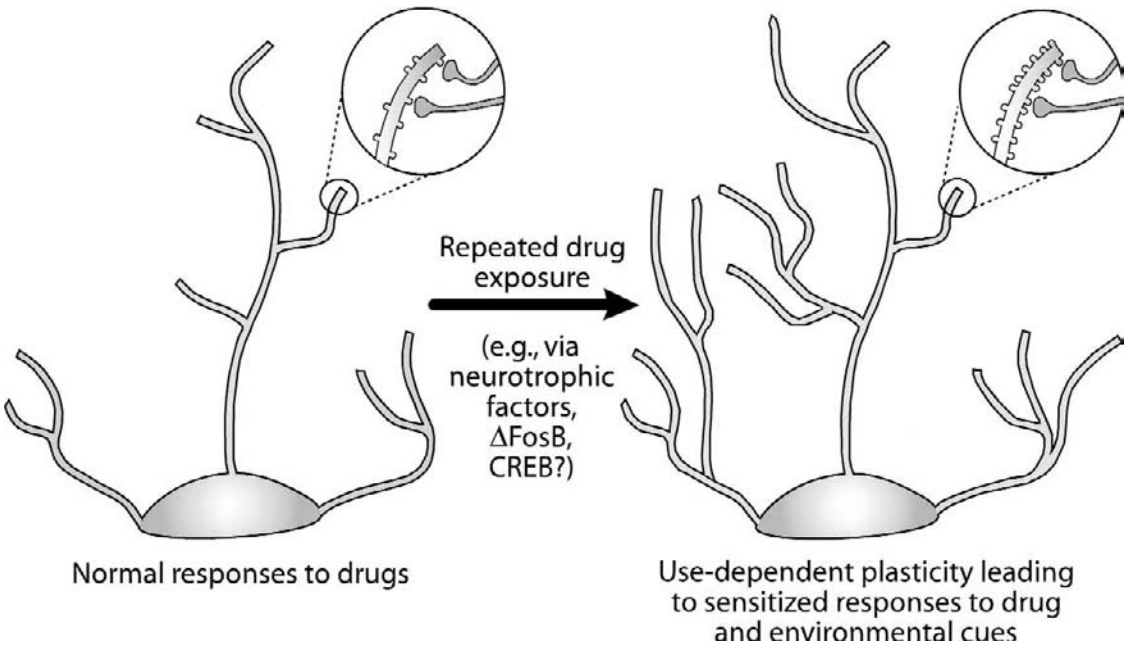

Figure 129-5 Regulation of dendritic structure by drugs of abuse. Expansion of a neuron's dendritic tree after chronic exposure to a drug of abuse, as has been observed in the NAc and prefrontal cortex for cocaine and related psychostimulants. The areas of magnification show an increase in dendritic spines, which is postulated to occur in conjunction with activated nerve terminals. Such alterations in dendritic structure, which are similar to those observed in some learning models (e.g., long-term potentiation), could mediate long-lived sensitized responses to drugs of abuse or environmental cues. (Reproduced with permission from Nestler EJ. Molecular basis of long-term plasticity underlying addiction. Nat Rev Neurosci 2001;2:119–128. Copyright Nature Publishing Group.) CREB, cAMP response element-binding protein.

behavioral actions of drugs of abuse, whereas infusion of glial cell line-derived neurotrophic factor exerts the opposite effect. Moreover, chronic administration of opiates or cocaine causes alterations in the intracellular signaling cascades for both of these neurotrophic factors, as well as changes in other neurotrophic factor systems. The results suggest a scheme whereby drug exposure perturbs neurotrophic factor signaling, which then disrupts the homeostatic role normally subserved by these factors in maintaining neuronal function. Given the ability of neurotrophic factors to mediate permanent changes in the brain during development, it is possible that analogous mechanisms contribute to stable changes in the adult brain that are related to addiction.

Although the molecular mechanisms underlying cocaine-induced changes in dendritic structure in the NAc and prefrontal cortex are not known, research has suggested one possible scheme. Chronic cocaine administration, via ΔFosB, increases levels of Cdk5 within the NAc and related striatal regions, and infusion of an inhibitor of Cdk5 into the NAc prevents the ability of cocaine to increase dendritic spine density in this brain region. The implication of these findings is that some of the structural changes caused by repeated cocaine administration may be mediated via induction of ΔFosB and may persist long after the ΔFosB signal itself dissipates (*see* Fig. 129-5).

FUTURE CONSIDERATIONS

Schemes discussed in this chapter are under evaluation to explain, at the molecular and cellular level, the highly stable behavioral abnormalities that define an addicted state. As knowledge of the neurobiological basis of addiction becomes more complete, it can be exploited to develop more effective treatments and ultimately preventive measures for addictive disorders.

Answers to another key question in the study of addiction will be critical for the understanding of addiction and for the development of new strategies for clinical management: Why do some individuals transition from casual drug use to compulsive use (addiction) so readily, yet others are highly resistant? Epidemiological studies show that addiction is highly heritable, with 40–60% of the risk for addiction to opiates, cocaine, nicotine, and alcohol being genetic. However, the individual genetic variations that comprise this risk have not been identified. Discovery of the genes involved will make it possible to better grasp the nongenetic factors that are also important. Such discoveries may allow individuals at risk for addiction to be targeted for prevention, and treatments for addiction to be targeted to certain individuals based on the underlying pathophysiology of their disorder.

130 Autism and Related Disorders

LINMARIE SIKICH, THOMAS H. WASSINK, KEVIN A. PELPHREY, AND JOSEPH PIVEN

SUMMARY

The search for the molecular basis of autism is challenging. The high heritability of the disorder led to great optimism that traditional linkage methods would rapidly identify disease genes for this phenotypically complex disorder and provide a means for understanding its underlying pathophysiology in the same way that the identification of the MeCP3 gene provided the impetus for major advances in the understanding of Rett Syndrome. Similarly, structural neuroimaging studies and neurochemical investigations of serotonin initially met with considerable optimism. In each of these cases, unexpected deficiencies of the methods coupled with heterogeneity in autism limited progress. Researchers have responded by developing more sensitive methods and by more precisely defining subject and control groups with particular attention to narrowly defined phenotypes, age, cognitive ability, and gender. There has been particular emphasis on taking a developmental perspective, especially regarding imaging and studies of brain chemistry and function.

Key Words: Autism; basal ganglia; brain size; *centaurin γ-2*; corpus callosum; epidemiology; medial temporal lobe; neuroimaging; tuberous sclerosis.

INTRODUCTION

Autism is associated with abnormalities in key aspects of human behavior from the earliest stages of development throughout the life span. It is among the psychiatric disorders most strongly influenced by genetic factors. Although the understanding of the genes and molecular mechanisms involved in the pathogenesis of autism remains limited, several chromosomal regions have been identified that likely harbor autism susceptibility genes. Neuropathological studies have identified subtle differences in the number, morphology, and organization of neurons in specific brain regions. Modest changes exist in the level of expression of multiple molecules involved in neural development and neurotransmission. Structural neuroimaging studies have identified abnormalities in brain growth trajectories and have suggested that these trajectories may differ across substructures and tissues. Functional imaging studies have identified activation patterns in response to specific stimuli that reflect abnormalities in several key neural systems. Integration of findings across gene-brain-behavior studies is likely to provide important insights into the pathogenesis and neural mechanisms underlying this complex neurodevelopmental syndrome.

CLINICAL PHENOMENOLOGY OF AUTISM

Autism is a complex developmental disorder defined by onset of clinical symptomatology before 3 yr of age in three behavioral dimensions:

1. Reciprocal social interaction.
2. Communication.
3. Stereotyped and/or repetitive behaviors and interests.

Although the behaviors observed in each of these areas are qualitatively different from those observed in typical development and are associated with functional impairment, there is considerable heterogeneity in the specific symptoms observed across affected individuals and during different developmental stages. For instance, some individuals with autism are completely uninterested in other people, and others may actively desire social relationships, but have no understanding of common social rules. Likewise, some may be nonverbal, although others have good vocabulary but marked pragmatic language deficits. Repetitive behaviors and interests range from repetitive motor movements and preoccupation with isolated sensory stimuli to extreme resistance to changes in the environment or in routine to being extremely focused on narrow areas of interest. Behavioral symptoms may vary during the course of development (e.g., motor stereotypies are particularly common in preschool children with autism, but are often absent in adults with autism).

The concept of autistic disorder has broadened to include individuals with behavioral deficits that are milder but qualitatively similar to those observed in classic autism. This range of conditions, often referred to as "Autism Spectrum Disorders," includes the subcategories of classic autism, pervasive developmental disorders not otherwise specified (PDD-NOS), and Asperger Syndrome. Asperger Syndrome is characterized by problems with pragmatic language, social reciprocity, and very restricted interests with language abnormalities limited to pragmatic use of language. However, the validity of these subgroup distinctions has not been established. Others have suggested that autistic traits are dimensional characteristics distributed throughout the population and that the underlying genetic liability may simply represent the extreme of normal genetic variation. Diagnostic thresholds are

generally based on degree of clinical impairment and, therefore, may not be the best phenotypes for use in studies examining pathogenesis (e.g., genetic linkage studies).

EPIDEMIOLOGY

Early epidemiological studies estimated classic autism prevalence at 2–5/10,000, with approx 70% of those with autism having mental retardation. Four times as many males as females are affected, although this difference is reduced among individuals with more severe degrees of mental retardation. Recent studies found the prevalence of autistic disorders to be higher (i.e., 7.5–17/10,000), with the proportion of those with mental retardation at approx 30%. The prevalence of all autism spectrum disorders has recently been estimated at 17–60/10,000. It remains unclear whether current studies reflect increased detection and broadening diagnostic schemes, or whether they reflect a true increase in the prevalence of the disorder. This question is the subject of several large-scale studies. Although the nature of this increased prevalence is not clear, numerous unsubstantiated hypotheses suggesting a variety of environmental agents (e.g., increased use of the measles-mumps-rubella vaccine) have been proposed.

ETIOLOGICAL HETEROGENEITY IN AUTISM Approximately 10% of autism cases occur in association with an identified medical condition thought to play a role in the pathogenesis of the autistic symptoms; the remaining 90% are idiopathic. Exposures that have been associated with autism include congenital rubella and exposure to thalidomide during the first trimester. There are case reports of multiple different chromosomal abnormalities in individuals with autistic spectrum disorders. Twelve reports have focused on abnormalities involving chromosome 15q11-q13, which some investigators found in up to 3% of their patients with autism. Finally, several single gene disorders including tuberous sclerosis, Smith-Lemli-Opitz Syndrome, Rett Syndrome, and Fragile-X syndrome have been associated with autistic symptoms. Although each of these single gene disorders accounts for a very limited number (3% or fewer) of autism cases, the neurodevelopmental models they provide have the potential to advance understanding of autism's underlying pathophysiology.

GENETICS OF AUTISM AND RELATED DISORDERS

SINGLE GENE DISORDERS ASSOCIATED WITH AUTISTIC SYMPTOMS: POSSIBLE MOLECULAR MECHANISMS FOR AUTISM The association of tuberous sclerosis with autism is well described with multiple studies reporting prevalence rates of autism of 20% in individuals with tuberous sclerosis and rates of tuberous sclerosis in autism of 3%. Neurofibromatosis, a closely related neurocutaneous disorder, is associated with autistic-like symptoms particularly in the social domain, but not with frank autism. Both disorders result in macrocephaly and various brain lesions including tubers, which are regions of cortical dysplasia thought to reflect aberrant neuronal migration, subependymal nodules, giant cell astrocytomas, and optic gliomas. Tuberous sclerosis results from mutations in two genes that appear to function as tumor suppressor genes. The TSC2 gene includes a GTPase-activating protein domain. In neurofibromatosis, a mutated GTPase-activating protein domain is unable to normally downregulate Ras activity. Upregulation of Ras activity in Nf1 mice is associated with learning deficits; blockade of Ras signaling in the Nf1 mice reverses the learning deficits. In addition, absence of Ras in Nf1 mice normalizes changes in long-term potentiation, which has been associated with synaptic plasticity. Further, it is possible that similar upregulation of proto-oncogenes such as Ras may be associated with some of the autistic features observed in tuberous sclerosis.

Rett Syndrome, an X-linked neurodevelopmental disorder, is classified as a pervasive developmental disorder as a result of transient expression of autistic symptoms in all three domains during early childhood. However, Rett Syndrome is distinguished from classic autism by the course of the autistic and neurological symptoms. In Stage III, there is a notable amelioration of autistic features, although there is progressive loss of language, purposeful hand movements, and gait disturbances. The gene causing Rett Syndrome has recently been identified at Xq28. It encodes methyl-CpG-binding protein 2 (MeCP2), which specifically binds to methylated DNA, and is presumed to act as a transcriptional repressor. It is hypothesized that mutations in the MeCP2 lead to inappropriate activation of genes. Neurons appear to have a special and enduring requirement for proteins like MeCP2 that bind methylated DNA.

Neuropathological and magnetic resonance studies in Rett Syndrome demonstrate decreased brain volume, especially in the frontal cortex, caudate, and midbrain. Neuron size is decreased with increased cell packing density. In specific regions including prefrontal cortex, dendrites appear less complex than normal with fewer dendritic spines. Reduction also has been reported in levels of nerve growth factor and microtubular-associated protein-2, which is important in dendritic development. There is evidence from microarray and electrophysiological studies that genes specific to excitatory neurotransmission and synaptic development are more likely to be expressed inappropriately when MeCP2 is abnormal or absent. These findings have led to the suggestion that mutations in the MeCP2 protein cause age-related disruption of synaptic proliferation and pruning in the first decade of life.

Fragile-X syndrome occurs in 1/2000–5000 live births and results in characteristic physical anomalies, mental retardation, and behavioral problems with attention, hyperarousal, and social anxiety. Of individuals with Fragile X, approx 1/3 meet criteria for autistic disorder, whereas about 2.5% of individuals with autism have Fragile-X syndrome. Fragile X is caused by the loss of the Fragile-X mental retardation protein (FMRP), as a result of abnormal hypermethylation and transcriptional silencing of the FMR1 gene. FMRP is expressed at highest levels in neurons within the hippocampus, cerebellum, cerebral cortex, entorhinal cortex, striatum, and thalamus. FMRP binds RNA, and appears to play a role in the regulation of local protein synthesis within dendritic spines. Reduced levels of FMRP appear to lead to translational misregulation of mRNA in the synapse, and, as a consequence, to abnormalities in synaptic development and neuronal plasticity. Postmortem studies of humans and mice lacking FMRP have identified consistent abnormalities in the number and morphology of dendritic spines. Immature shapes predominate, suggesting impairment in normal spine maturation and disruption of synaptic pruning. A complex environment, which presumably provides increased afferent input, is associated with increased levels of FMRP in rats, providing evidence of behaviorally-induced alteration of FMRP expression. Such increases in input have also been associated with a reduction in dendritic spines and are consistent with increased synaptic pruning. In addition, the absence of characteristic learning deficits in FMR1 knockout mice bred on specific hybrid backgrounds, suggests that functional interactions between the FMR1 gene and other genes or their gene products or both are functionally important.

In each of the neurodevelopmental models provided by single gene disorders associated with autism, mutations affect the regulation of other genes that are important in neuronal development or activity. In two cases, there is upregulation of interacting proteins, in the other downregulation. In all cases, synaptic plasticity appears to be involved, suggesting that many different molecules are likely to be critically involved in the refinement of synapses during development and emphasizing the potential importance of such molecules in autism.

GENETIC BASIS OF IDIOPATHIC AUTISM Studies examining the rates of autism in siblings and twins of affected individuals provide evidence of autism's strong genetic foundation. In the 1980s, the risk of autism among siblings of affected individuals was approx 4–5% compared with a risk in the general population at that time of 0.02–0.05%. Thus, the sibling relative risk (SRR = sibling risk/general population risk) is approx 100, the highest known SRR for any psychiatric disorder. Twin studies compare concordance rates between monozygotic and dizygotic cotwins of affected individuals to arrive at an estimate of the proportion of phenotypic variance attributable to genetic, as opposed to environmental, etiologies, which is known as the heritability estimate. Twin studies of autism reveal monozygotic concordance rates ranging between 73 and 95% and dizygotic rates from 0 to 24%, producing heritability estimate greater than 90%.

GENETIC MECHANISMS—MULTIPLE COMPLEXITIES The high SRR and heritability of autism gave rise to optimism that autism genes would be relatively easy to find. However, no autism susceptibility gene has been definitively identified. The obstacles to success include phenotypic complexity, the limited statistical power of sib-pair linkage analyses, and genetic complexity. The phenotypic complexity of autism leads to difficulty in determining whether individuals with less severe or pervasive symptoms are affected. Because many parents of children with autism limit further childbearing and individuals with autism seldom have children, large, multigenerational pedigrees are extremely rare in autism. Consequently, most linkage studies of autism examine families in which at least two siblings have the disorder. Such affected sib-pair analyses have the least statistical power of any method examining linkage. Family study data has suggested the likely existence of multiple genes, which may interact additively, multiplicatively, or epistatically (in which one variant contributes to susceptibility only if a second specific variant is present). In addition, genetic variations outside the coding region that affect promoter, enhancer, and/or splicing activity and repetitive elements that increase the risk for chromosomal abnormalities may also increase disease vulnerability. Finally, it is likely that different combinations of genes contribute to susceptibility in different populations. Consequently, different loci will occur and be identified in different samples. Thus, the expectation of replicating even true linkages is unrealistic and failure to replicate should not be assumed to negate prior findings.

In spite of these difficulties, a growing number of linkage studies of autism have been performed, some of which have produced credible evidence for disease susceptibility loci as summarized in Table 130-1. The loci on chromosomes 7q, 2q, and 15q are particularly compelling. Additional regions have been implicated on virtually all the chromosomes, though the implicating evidence is rarely compelling or conclusive.

Chromosome 7q The first autism linkage study reported its strongest evidence for linkage to a wide region of chromosome 7q. Six subsequent studies have reported evidence for linkage and/or linkage disequilibrium to various regions of 7q. Reports also exist of autistic individuals with chromosomal abnormalities in this region and of linkage and linkage disequilibrium of speech and language disorders other than autism to 7q. The region of interest spans more than 50 centimorgans. Numerous 7q candidate genes have been tested, with none showing a clear or consistent contribution to susceptibility.

Chromosome 2q Evidence for linkage to a distal region of chromosome 2q has been reported in a number of linkage studies. In addition, a growing number of deletions of the tip of 2q are being identified in autistic individuals. There is increasing evidence to support the roles of a developmentally regulated gene on the terminal portion of chromosome 2 (2q37.3), the gene *centaurin γ-2(CENTG2)* as a contributor to autism susceptibility. Several of the breakpoints identified among individuals with autism and terminal chromosome 2 abnormalities were within or immediately upstream of *CENTG2*. Involvement of *CENTG2* was assessed by screening its exons for variants in 135 unrelated autistic individuals and 160 nonautistic control subjects, and by assessing six intragenic polymorphisms for linkage and linkage disequilibrium in 60 autism-affected sibling pair families. Five polymorphisms with potential functional implications were identified on the exon screen. In addition, strong evidence for linkage emerged with a maximum two-point heterogeneity-logarithmic odds value of 4.2 from a polymorphism in intron 10. No evidence for linkage disequilibrium was identified at any of the markers tested. It is unclear whether the linkage to *CENTG2* and the previously reported linkages to distal chromosome 2q are related because there is a significant difference between the two regions.

Chromosome 15q Chromosome 15q11-13 has received attention primarily because small maternally derived, chromosomal duplications in this region have been associated with autism. However, evidence of linkage to the region was weak using traditional phenotypic definitions of autism. However, another study that incorporated phenotypic information related to personal rigidity, found strong evidence for linkage disequilibrium. Screening of specific candidate genes has been largely negative.

Statistical Genetics The first impulse when addressing the generally equivocal results characteristic of linkage screens from genetically complex disorders is to increase the sample size by recruiting additional families or by combining data from all existing samples into one. This, intuitively, should increase the ability of the analyses to detect genes that produce real but small contributions to susceptibility. Unfortunately this approach, rather than revealing previously hidden disease loci, tends to actually diminish linkage signals as a result of heterogeneity. An intriguing, alternative approach is to integrate results from independent studies sequentially rather than in a pooled fashion. This method is in the process of being applied to autism linkage data. Yet another approach is to estimate the posterior probability, rather than the likelihood, of linkage.

Phenotypic Approaches Idiopathic autism is likely to be heterogeneous, combining multiple phenotypes with potentially distinct genetic etiologies under a broad, syndromic diagnosis, thereby hindering the ability of linkage analyses to detect those loci. Furthermore, the arbitrariness of having a set number of severe enough symptoms to qualify for the diagnosis excludes individuals with less dramatic, but possibly genetically related disturbances. Two complementary approaches, subgrouping families based on phenotypic characteristics of the probands, and including

individuals with the Broader Autism Phenotype are being implemented to address these difficulties.

Subgrouping involves categorizing families within a study sample based on endophenotypes that are suspected of having independent genetic etiologies. The most common endophenotypes used thus far in autism relate to language. Families in affected sib-pair linkage samples have been separated into two groups based on whether both children have severe phrase speech delay or not, with the hope that both subgroups will be more homogeneous than the combined group. Use of this specific endophenotype has dramatically influenced linkage data in at least three separate studies, with the language impaired subgroups demonstrating significantly stronger evidence for linkage than the combined samples from which they were drawn. Recently, "rigidity" in probands has been examined with similar benefit.

Similarly, the broader autism phenotype has been used to gain more information from pedigrees. For example, classifying parents in affected sib-pair families as *affected* or *unaffected* based on whether they had difficulties with specific aspects of language as children rather than as *unknown* significantly increased the linkage signals in a language impaired subgroup of families in two previously implicated regions of interest. Further, this approach elicited additional information from an existing sample without the expenditure of effort required to ascertain and enroll new families.

Molecular Approaches Improved statistical and phenotypic approaches will almost certainly enhance the ability to identify autism disease genes. They are unlikely, however, to completely overcome the challenges named earlier; chromosomal regions of interest will continue to contain many candidate genes, all of equal merit, and genes of weak effect will thwart detection by current methods. However, additional molecular methods are being developed that will enhance the ability to overcome such challenges. These include enhanced detection of chromosomal abnormalities, case–control association studies using single-nucleotide polymorphisms (SNPs), and development of more appropriate animal models of autism.

Chromosomal abnormalities provide valuable clues to the location of potential susceptibility genes. With traditional karyotyping techniques, it is difficult to detect abnormalities that are smaller than 2 Mb, are in regions that are gene rich or have indistinct banding patterns, or are in telomeric and subtelomeric regions, which are prone to small deletions. Recently, panels of fluorescence-*in situ* hybridization probes specific for telomeres have been developed. Studies using them to screen populations of individuals with previously unexplained mental retardation have found that 5–20% have subtelomeric abnormalities that were not detected by high-resolution karyotyping. Small pilot studies have demonstrated this technology's efficacy in autism, and large-scale investigations are underway.

A case–control association study, which compares genotypes of probands and normal controls drawn from the same demographic population, is easier and less expensive to gather than affected sib-pair families. Such studies of closely spaced SNPs may enable more

accurate refinement of initial linkage findings. Although unsuitable for linkage studies, case–control samples are useful for combing through regions of interest within linked intervals. SNPs are more common and more stable than the microsatellite polymorphisms typically genotyped in linkage studies, and therefore, enable more accurate and defined localization of disease gene variants.

Animal models of genetic abnormalities, which have assisted identification and characterization of numerous disease genes, have seldom been utilized in psychiatric disorders because of difficulties in defining the mouse phenotypes relevant for psychiatric disorders. However, assays for traits relevant to autism such as social activity, rigidity, and anxiety are being developed in mice. Technology is available that can limit the timing and location of altered genetic activity in mice, which is particularly important for neurodevelopmental disorders. Technologies have already generated data suggesting specific genes, such as those in the Wnt/disheveled/β-catenin and oxytocin/vasopressin biomolecular pathways, as candidate disease genes for autism.

NEUROPATHOLOGY OF AUTISM

Neuropathological studies in autism have been limited by the availability of only a small number of brains from individuals with this disorder. The brains studied have been from individuals of diverse ages, who are predominately mentally retarded. The two most comprehensive studies involve only 11 subjects. Despite this, a number of findings have emerged that suggest subtle, regional disruptions in the size and complexity of individual neurons, the number of neurons, and the organization of neurons. Although the cerebellum has consistently shown changes in autism, findings in other brain regions appear more variable. The number and density of cerebellar Purkinje cells was consistently reduced compared with controls. In other regions of the cerebellum, children were noted to have unusually large neurons, whereas adults had neurons with smaller cell bodies. Because there is a 1:1 correspondence between neurons in the inferior olive and the Purkinje cells, the normal numbers of inferior olive cells and absence of gliosis have been cited as evidence that brain abnormalities in autism occur very early in development. However, it is also possible that the inferior olive neurons survive because each inferior olive neuron connects to multiple Purkinje cells. In the hippocampus, amygdale, and entorhinal cortex, subjects had unusually small neurons. In the hippocampus, these neurons appeared to have less complex dendritic trees than neurons from control subjects. One research group found these neurons were densely packed although another study found no changes in unit density. There have also been isolated case reports of brainstem abnormalities.

Isolated areas of cortical dysgenesis with abnormal gyral patterns, disrupted laminar boundaries and abnormally oriented pyramidal cells have been noted in frontal, temporal, and cingulate regions. Advances in analysis methods show significant differences in cortical minicolums. These minicolumns appear to be the fundamental organizational unit of the cortex and consist of a neuron-rich core that also contains cortical efferents and cortico-cortical fibers, bounded by vertical, inhibitory fiber bundles from γ-aminobutyric acid (GABA)-ergic interneurons and surrounded by a cell-poor area that is rich in dendritic arborizations and unmyelinated axons. Minicolumn size is evolutionarily highly conserved. It has been hypothesized that minicolumns are critical in ensuring appropriate thalamocortical connectivity. Individuals with autism have more minicolumns per unit area and the core areas are larger with fewer cells, although the cell-poor areas are significantly smaller than in matched controls. It is not yet known whether the total number of thalamic afferents is similar to controls. However, if it is, these changes in minicolumn organization would lead to innervation of a larger number of cortical units by the same thalamic afferent and reduce the specificity of inputs.

CHANGES IN PROTEINS AND NEUROTRANSMITTERS IN AUTISM Studies of specific proteins and neurotransmitters in autism have been limited by difficulties in assessing brain levels of molecules in vivo and/or by the scarcity of postmortem tissue. However, there have been a number of PET, serum, and postmortem studies examining various molecules thought to be important in neurodevelopment or neurotransmission. These studies have revealed modest differences, typically in the range of a 40–50% change in the level of several molecules. These molecules include reelin (which is important in cortical layering), B-cell leukemia/lymphoma 2 (an apoptosis regulator), and Neural Cell Adhesion Molecule (NCAM-180d form, which is involved in neurite outgrowth and synaptic plasticity).

Several systems show modest differences from control samples in the expression of neurotransmitter related molecules, although the significance of these findings is unclear. There appear to be changes in GABA-ergic transmission in the hippocampus with decreases in glutamic acid decarboxylase, which converts glutamate to GABA, and reduced binding to GABA(A) and benzodiazepine receptors reported. Changes in the cholinergic system have been reported in the frontal and parietal cortices. Specifically decreases in receptor binding of approx 30% for muscarinic M1 receptors and of approx 70% for nicotinic receptors have been reported. In cerebellar tissue, increased activity of the glutamate system has been reported with increased expression of the excitatory amino acid transporter 1 gene and the α-amino-3-hydroxy-5-methyl-4-isoxazole propionate 1 glutamate receptor. In contrast, no changes in the binding of serotonergic, cholinergic, and glutaminergic ligands in the hippocampi of autistic individuals were observed.

Changes have also been reported in the serotonergic system of individuals with autism. The observation that approx 33% of individuals with autism have hyperserotonemia is longstanding. However, PET scans studying serotonin synthesis in the brain revealed an abnormal spatial distribution of serotonin synthesis in a pathway connecting the dentate nucleus of the cerebellum, the thalamus, and frontal cortex with decreased levels of synthesis in the cortex and thalamus and increased levels in the contralateral cerebellum. A difference has been found in the developmental pattern of serotonin synthesis between individuals with autism and controls with typical development. Normally, serotonin synthesis is 200% the adult levels until 5 yr of age, and gradually falls to adult levels over the next several years. However, in individuals with autism levels are very low until approx 9 yr of age and then increase to about 150% of the normal adult levels. The typical developmental pattern of serotonin synthesis is very similar to the developmental patterns of synapse formation and elimination with many synapses during early childhood that are gradually eliminated during the second decade of life.

STRUCTURAL BRAIN IMAGING IN AUTISM

Structural imaging of the brain is ideally suited for the study of a phenotypically complex, etiologically heterogeneous, neurodevelopmental disorder such as autism, where the changes in neuroanatomy over time can be characterized in large numbers of affected individuals from the earliest ages of diagnosis. However, as a result of a lack of standardized diagnostic criteria and assessment

protocols, small sample sizes, inclusion of heterogeneous populations (e.g., autistic subjects with associated medical conditions), failure to account for a number of confounding factors (e.g., gender, IQ, overall brain size) and the technological limitations of the available MRI hardware and image processing software, early MRI studies of autism failed to generate consistent findings. More recent studies have documented an increase in brain size in autistic individuals along with abnormal size of other structures (e.g., basal ganglia, corpus callosum [CC]) that may provide important insights into the brain phenotypes and underlying neural development.

BRAIN SIZE IN AUTISM About 20% of autistic individuals have macrocephaly. Increased brain size was reported in two independent samples of autistic individuals contrasted with independent comparison groups that were sensitive to gender, cognitive level, age, and socioeconomic status. Increased lateral ventricular size was proportionate to the overall increases in brain size.

TIMING OF BRAIN SIZE ENLARGEMENT Chart reviews suggest that individuals with autism often have enlarged head circumference at birth, but do not develop frank macrocephaly until the first few years of life. Because the rate of brain growth may be increased during the early postnatal period, several groups have attempted to examine age effects. Brain volume on MRI was studied in a cross-sectional sample of 60 males with autism and 52 "normal" controls, all of whom were divided into two age groups: 2–4 and 5–16 yr of age. Analysis of the 2–4-yr-old group revealed significant brain volume enlargement in individuals with autism compared to controls, with significant increases in both gray and white matter volume; whereas in the older group, brain volumes in the autistic group were either smaller or no different than controls. Analysis of a subset of these subjects (12, 2–4-yr-old autistic individuals vs 8, 2–4-yr-old controls) showed an increased gray matter volume in the frontal and temporal lobes only and an increased white matter volume in frontal and parietal lobes. Brain volume enlargement on MRI has also been independently demonstrated in 3–4 yr olds with autism. Finally, enlargement of the total temporal and parietal lobe volumes, but not frontal lobe volumes, has been demonstrated in a sample of adolescents and adults with autism.

Overall these studies provide converging evidence for brain volume enlargement in autism. However, the timing and nature of this enlargement are unclear. Longitudinal studies will be necessary to clarify the timing of this phenomenon. Elucidation of the timing and pattern of enlargement across tissues and structures may provide insight into underlying mechanisms that may be responsible for the abnormality as well as clues for candidate genes involved in determining particular patterns of brain development.

CEREBELLUM Although postmortem studies have consistently shown abnormal loss of Purkinje cells in the cerebellum, and a highly visible study reported decreased size of the neocerebellar vermis on MRI in autism, numerous independent attempts at replication have not provided support for the observation of neocerebellar hypoplasia in autism. However, two studies have found evidence for an increase in overall cerebellar volume that appears to be proportionate to the overall increase in total brain volume in autistic individuals.

MEDIAL TEMPORAL LOBE STRUCTURES The medial temporal lobe has been implicated in autism because of its role in social behavior and cognition in human and animal lesion studies, and the finding of postmortem abnormalities. Increased amygdala volumes were found in 44, 3–4-yr-old children with autistic spectrum disorders compared to developmentally delayed, nonautistic controls. Further the increased amygdala volumes largely resulted from a subset of 31 children with autism and were not present in a more mildly affected group of 14 children with PDD-NOS. Results of other studies have varied, showing increases, decreases, and no differences in amygdala volume. No consistent volume abnormalities have been reported in MRI studies of the hippocampus in autistic individuals. Finally, consistent with PET and postmortem studies, the anterior cingulate was noted to show a decreased volume in autistic individuals on MRI in one study. Given the diversity of results, small sample sizes and lack of longitudinal examination across a range of ages, no firm conclusions can be drawn about the size of medial temporal lobe structures on MRI in autism.

BASAL GANGLIA Structural studies of the basal ganglia in autism are particularly interesting because volumetric changes in these structures have been consistently described in obsessive-compulsive disorder and Tourette's syndrome, disorders that overlap phenomenologically with the ritualistic, repetitive behaviors seen in autism. Increased caudate volume and stereotyped behaviors have also been correlated in Fragile-X syndrome. Enlargement of the caudate, but not the globus pallidus or putamen, was detected in two independent samples of autistic individuals. In addition, there were significant correlations between caudate size and stereotyped-repetitive behaviors ($r = 0.5$), but not social or communication deficits. These data suggest the possibility that two different frontal—striatal mechanisms, one involved with motor stereotypies (positively correlated with caudate volume) and the other involved in compulsive and ritualistic behavior (negatively correlated with caudate volume), might be operating in autism.

CORPUS CALLOSUM The CC is the major axonal pathway linking the two hemispheres. Abnormalities in the CC are hypothesized to index disruption in cortical connectivity. Further, the axons crossing in the CC are known to be topographically related to their origins in the cerebral cortex, providing the potential to narrow the cortical regions implicated through an examination of the size of subsections of the corpus callosum. A reduction in CC size in autism is well established. These findings are of increased interest because CC enlargement would be expected given the evidence for increased brain volume. The discrepant findings of enlarged brain volume and reduced CC size may provide an index of overall disconnectivity in autism, or provide clues to particular cortical layers that may be implicated in the increased brain size, as only selected layers (e.g., cortical layer III) contribute axons that cross at the CC. However, consistency is lacking regarding which subsections are implicated.

NEUROPSYCHOLOGICAL CHARACTERISTICS ASSOCIATED WITH AUTISM

Individuals with autism appear to have problems both attending to socially salient stimuli and making inferences about the mental states of others in specific social situations. In contrast to normal controls that focus on the eyes and mouth of people when looking at faces, individuals with autism focus on peripheral parts of the face such as the ears and chin and avoid the eyes (Fig. 130-1). This tendency is maintained when people with autism evaluate social interactions between people, in contrast to controls who focus on the eye gaze between people. Investigators have also found differences in the extent to which individuals with autism are aware that others

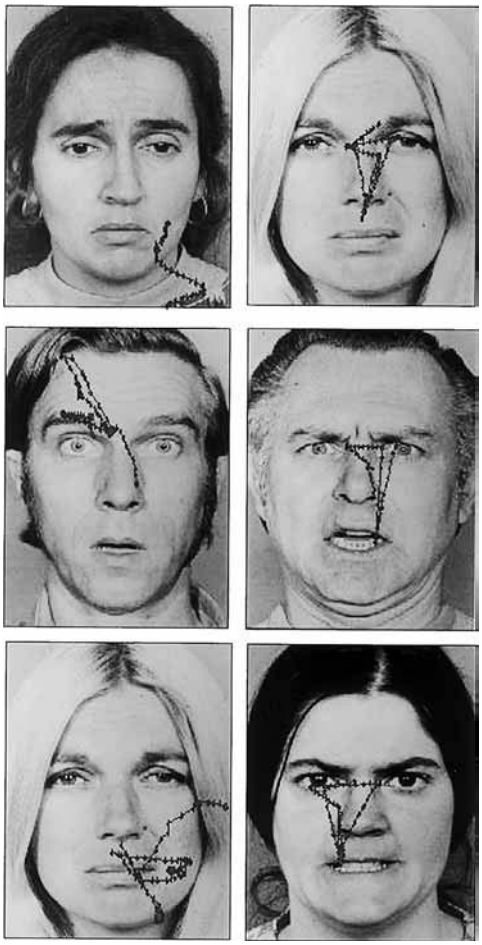

Figure 130-1 The visual scan paths utilized to inspect still pictures of faces by three individuals with autism are shown on the left. These scan paths avoid the eyes and nose in stark contrast to the scan paths of three typically developing controls (on the right). (Reproduced with permission from Pelphrey KA, Sasson NJ, Reznick JS, Paul G, Goldman BN, Piven J, Visual scanning of faces in adults with autism. J Autism Dev Disord 2002:32[4]:249–261.)

may have perceptions and beliefs that differ from their own because the others have access to different information or experiences. This awareness, known as a theory of mind, is critical to empathy and truly reciprocal interactions. However, this ability is clearly influenced by one's developmental level. Social cognition appears to involve a widely distributed neural network in which the amygdala, temporal cortex, and orbitofrontal regions play central roles.

Central coherence refers to the ability to process information within a contextual context. People with autism appear to show a processing bias in favor of featural information at the expense of configural information. They often excel at the Wechsler Block Design subtest and the embedded figures test, easily breaking the whole figures into parts. However, this detail-focused processing style leads to poor performance on other tasks in which processing in context is necessary. Prefrontal cortex appears important in the processing of contextual information in control subjects, whereas the right hemisphere, particularly the somatosensory cortex, has been implicated in problems of central coherence.

Executive function is specifically conceptualized as involving several overlapping, but potentially dissociable mental operations, such as cognitive flexibility, planning, inhibition of prepotent responses, and working memory. Executive functioning deficits are observed in multiple neuropsychiatric and neurodevelopmental conditions, and do not appear directly related to IQ. Individuals with autism have been shown to have particular difficulty with cognitive flexibility as assessed by the ability to readily shift from one set of rules to another in multiple studies. In addition, autistic individuals also appear to perform poorly on tasks that simultaneously tax both planning and inhibitory control. Difficulties with cognitive flexibility, response inhibition, and working memory have been independently correlated with ritualistic and repetitive behaviors in autism. Difficulties in executive function have also been related to difficulties in social behavior in autism. Impairments of executive function in neurodevelopmental disorders appear to arise from abnormalities in the pathways connecting frontal cortex and subcortical structures (e.g., fronto-striatal system).

FUNCTIONAL NEUROIMAGING IN AUTISM

Functional neuroimaging findings in autism have been focused on studies of simple motor actions, the embedded figures task, language processing, and social cognition. The potential of functional neuroimaging studies to illuminate the neural basis of specific domains of behavior in autism is well illustrated by studies of social cognition. For example, neuroimaging studies of typically developing individuals have consistently identified a region on the lateral aspect of the fusiform gyrus that responds selectively to faces in contrast to nearby regions, including the inferior temporal gyrus, that are active during visual processing of nonface objects. In typically developing controls, activation of the fusiform gyrus is also modulated by the intentionality of socially relevant stimuli. The fusiform gyrus may be a critical component in the neural network involved in emotion recognition and social cognition. Specifically, the fusiform gyrus and the superior temporal cortices provide information about facial structure and movement to other brain structures especially the amygdala, which appears to connect the perceptual representation of a socially relevant stimulus to an emotional and social significance.

Individuals with autism have striking impairments in the processing of social and emotional information from faces. Three independent studies, all using slightly different face processing paradigms, have found that adult male participants with autism showed less activity in the fusiform gyrus and more activity in the inferior temporal gyrus than controls when looking at faces. The specific location of the evoked activity outside the fusiform gyrus was highly variable between different autistic subjects. These studies also demonstrated reduced amygdala activity during implicit processing of emotion from faces. Eye tracking studies also demonstrate that individuals with autism tend to inspect faces in an idiosyncratic, somewhat disorganized way in contrast to control subjects, who focus on the eyes and mouth. Collectively, these studies suggest a neural basis for the face processing deficits observed in individuals with autism. Based on these studies, postmortem studies in autism, and an animal model of early amygdala ablation, investigators have proposed that an early disruption in the amygdala and its connections to temporal cortices impairs the development of normal specificity in the fusiform gyrus.

Similarly, functional neuroimaging studies in individuals with typical development have found that frontal–temporal cortical regions and subcortical regions (including the left amygdala, hippocampus, and striatum; and the insula and superior temporal cortices bilaterally) are activated to a greater extent during theory of mind tasks than control tasks. However, when individuals with autism performed the same tasks, they failed to activate the

amygdala and had reduced activation of frontal cortex. In a similar PET study, individuals with autism had marked difficulty when asked to identify the intentions of animated, nonhuman figures, and had hypoactivation of medial prefrontal cortex, the superior temporal cortices, and the temporal pole near the amygdala.

One study of motor activation in autism found reduced activation overall in individuals with autism relative to controls. In addition, there was less deactivation of prefrontal cortex and greater individual variability of regional activation among subjects with autism. The existing embedded figures study also suggests that individuals with autism may utilize different brain regions for detail-oriented processing than controls. In the autism group, reduced activation was observed overall, particularly in the right dorsolateral prefrontal cortex and parietal cortices. However, there was greater relative activation of the right ventral occipital region among subjects with autism. The limited studies of language processing also show atypical activation patterns. The atypical findings included reversed or reduced hemispheric specialization, anomalous activation of cingulate cortex during a tone perception task, and reduced activation of the frontal-thalamic-cerebellar pathway in which abnormal serotonin synthesis has been demonstrated. Studies of language processing in autism are likely to be greatly enhanced by research aimed at dissecting the neural bases of pragmatic and semantic language skills in normal individuals.

CONCLUSIONS

The search for the molecular basis of autism is challenging. The high heritability of the disorder led to great optimism that traditional linkage methods would rapidly identify disease genes for this phenotypically complex disorder and provide a means for understanding its underlying pathophysiology in the same way that the identification of the MeCP3 gene provided the impetus for major advances in the understanding of Rett Syndrome. Similarly, structural neuroimaging studies and neurochemical investigations of serotonin initially met with considerable optimism. In each of these cases, unexpected deficiencies of the methods coupled with heterogeneity in autism limited progress. Researchers have responded by developing more sensitive methods and by more precisely defining subject and control groups with particular attention to narrowly defined phenotypes, age, cognitive ability, and gender. There has been particular emphasis on taking a developmental perspective, especially regarding imaging and studies of brain chemistry and function.

Exciting research is aimed at elucidating both the neural systems involved in specific aspects of the behavioral phenotype and basic neurodevelopmental processes likely to underlie the disturbances in these neural systems. Functional imaging studies of several different cognitive processes have found activation patterns in individuals with autism that differ from those robustly observed in typically developing individuals. Highly specialized areas such as the temporal fusiform gyrus during facial perception and the amygdala in theory of mind tasks appear to be less active in autistic individuals than typically developing individuals. Functional imaging studies have also shown great individual variability in the activation patterns of autistic individuals, which raises the possibility that individuals with autism may have difficulties developing appropriate functional specialization of cortical regions. Synapse refinement through pruning is thought to play a crucial role in the functional specialization of the cortex. There are intriguing, but indirect, leads that synapse refinement may be impaired in autism. First, increased cortical size could result from persistence of inappropriately large dendritic arbors during specific developmental periods. The changes described in the density and organization of cortical minicolumns in autism is also consistent with a reduction in cortical specialization. Finally, because serotonin plays a crucial role in cortical patterning, the developmental disturbances in serotonin synthesis reported in autism might lead to problems with synaptic pruning and cortical specialization. Similar problems might be caused by other abnormalities in neurotransmitter systems or neurodevelopmental molecules reported in autism. Aberrant synapse elimination might initially lead to more cells that receive less specific inputs and fail to establish appropriate and efficient connections with other components of key neural circuits (like the amygdala-temporal-frontal circuits involved in social cognition). Ultimately, cells with inadequate appropriate stimulation might atrophy or even die. Ongoing integration of the findings from genetic studies, structural, and functional neuroimaging and neurodevelopmental studies in relevant animal models and brain samples has great potential to provide insights into brain-behavior relationships and neural mechanisms in this complex neurodevelopmental disorder.

About the Editors

Marschall S. Runge, MD, PhD, was born in Austin, TX and graduated from Vanderbilt University with a BA in general biology and a PhD in molecular biology. He received his medical degree from the Johns Hopkins School of Medicine and trained in internal medicine at Johns Hopkins Hospital. He was a cardiology fellow and junior faculty member at the Massachusetts General Hospital. Dr. Runge's next position was at Emory University where he directed the Cardiology Fellowship Training Program. He then moved to the University of Texas Medical Branch in Galveston where he was Chief of Cardiology and Director of the Sealy Center for Molecular Cardiology. He joined the University of North Carolina (UNC) in 2000 as chairman of the Department of Medicine and in 2004 was also appointed president of UNC Physicians and Clinics. Dr. Runge is board certified in internal medicine and cardiovascular diseases and has spoken and published widely on topics in clinical cardiology and vascular medicine. He maintains an active clinical practice in cardiovascular disease and medicine, in addition to his teaching and administrative activities in the Department of Medicine.

Dr. Runge's basic research interests centers around atherosclerosis, thrombosis and vascular biology. He has published extensively and received both National Institutes of Health (NIH) and industry funding for his work in this area. He is a member of numerous grant review committees including those of the NIH and the American Heart Association.

Dr. Runge is also co-editor of *Netter's Internal Medicine, Netter's Cardiology,* and *Principles of Molecular Cardiology.* He has published nearly 175 articles in peer-reviewed journals, actively reviews articles for top publications, and serves on the Editorial Board for *Circulation, Circulation Research, Current Cardiology Reviews,* and *Arteriosclerosis, Thrombosis and Vascular Biology.* He is an active member of many prestigious academic medical societies and has given numerous lectures in the United States and abroad.

Cam Patterson was born in Mobile, AL and attended UMS Preparatory School, where he was a member of the state championship soccer team, class president, and valedictorian. He was a Harold Sterling Vanderbilt Scholar and studied psychology and English at Vanderbilt University, graduating Summa Cum Laude. He participated in the Honors Research Program at Vanderbilt and conducted research in behavioral pharmacology during that time. Dr. Patterson subsequently attended Emory University School of Medicine, graduating with induction in the Alpha Omega Alpha Honor Society, and completed his residency in internal medicine at Emory University Hospitals. He became the youngest ever chief resident at Grady Memorial Hospital at Emory University in 1992, supervising more than 200 house officers in four hospitals. He completed 3 years of research fellowship under the guidance of Edgar Haber at the Harvard School of Public Health, developing an independent research program in vascular biology and angiogenesis that was supported by an NIH fellowship.

In 1996, he accepted his first faculty position at the University of Texas Medical Branch, and in 2000 Dr. Patterson was recruited to the UNC at Chapel Hill to become the founding director of the Carolina Cardiovascular Biology Center. In 2005, he also became the chief of the Division of Cardiology at UNC. Dr. Patterson is the Ernest and Hazel Craige Distinguished Professor of Cardiovascular Medicine, and he has been recognized at UNC with the Ruth and Phillip Hettleman Prize for Artistic and Scholarly Achievement. He is an established investigator of the American Heart Association and a Burroughs Wellcome Fund Clinical Scientist in Translational Research.

Dr. Patterson is a member of several editorial boards, including *Circulation* and *Circulation Research,* and is an elected member of the American Society of Clinical Investigation and the Association of University Cardiologists. Dr. Patterson maintains active research programs in the areas of angiogenesis and vascular development, cardiac hypertrophy, protein quality control, and translational genomics and metabolomics. He is also the director of the Cardiac Genetics Clinic. He is married to Kristine Blair Patterson, MD, who is a member of the Division of Infectious Diseases at UNC and the medical director of the Wake County Health Department. They have three children, Celia Blair, Anna Alyse, and Graham Gehring.
